We describe a standard star catalog constructed using multiple SDSS photometric observations (at least four per band, with a median of ten) in the *ugriz* system. The catalog includes 1.01 million non-variable unresolved objects from the equatorial stripe 82 ($|\delta_{J2000}| < 1.266^\circ$) in the RA range 20h 34m to 4h 00m, and with the corresponding *r* band (approximately Johnson V band) magnitudes in the range 14–22. The distributions of measurements for individual sources demonstrate that the photometric pipeline correctly estimates random photometric errors, which are below 0.01 mag for stars brighter than (19.5, 20.5, 20.5, 20, 18.5) in *ugriz*, respectively (about twice as good as for individual SDSS runs). Several independent tests of the internal consistency suggest that the spatial variation of photometric zeropoints is not larger than ~ 0.01 mag (rms). In addition to being the largest available dataset with optical photometry internally consistent at the $\sim 1\%$ level, this catalog provides practical definition of the SDSS photometric system. Using this catalog, we show that photometric zeropoints for SDSS observing runs can be calibrated within nominal uncertainty of 2% even for data obtained through 1 mag thick clouds, and demonstrate the existence of He and H white dwarf sequences using photometric data alone. Based on the properties of this catalog, we conclude that upcoming large-scale optical surveys such as the Large Synoptic Survey Telescope will be capable of delivering robust 1% photometry for billions of sources.

Subject headings: surveys — catalogs — standards — methods: data analysis — techniques: photometric — instrumentation: photometers

1. Introduction

Astronomical optical photometric data are usually calibrated using sets of standard stars whose brightness is known from previous work. The most notable modern optical standard star catalogs are Landolt standards (Landolt 1992) and Stetson standards (Stetson 2000, 2005). Both are reported on the Johnson-Kron-Cousins system (Landolt 1983 and references therein). The Landolt catalog provides magnitudes accurate to 1-2% in the *UBVRI* bands for ~ 500 stars in the *V* magnitude range 11.5–16. Stetson has extended Landolt’s work to fainter magnitudes, and provided the community with ~ 1 -2% accurate magnitudes in the *BVRI* bands for $\sim 15,000$ stars in the magnitude range $V \lesssim 20$. Most stars from both sets are distributed along the Celestial Equator, which facilitates their use from both hemispheres.

The data obtained by the Sloan Digital Sky Survey (SDSS; York et al. 2000) can be used to extend the work by Landolt and Stetson to even fainter levels, and to increase

the number of standard stars to over a million. In addition, SDSS has designed its own photometric system (*ugriz*, Fukugita et al. 1996) which is now in use at many observatories worldwide. This widespread use of the *ugriz* photometric system motivates the construction of a large standard star catalog with $\sim 1\%$ accuracy. As a part of its imaging survey, SDSS has obtained many scans in the so-called Stripe 82 region, which is defined by $|\delta_{J2000}| < 1.266^\circ$ and RA approximately in the range 20h – 4h. These repeated observations can be averaged to produce more accurate photometry than the nominal 2% single-scan accuracy (Ivezić et al. 2004a).

The catalog and methods presented here have some similarity with an effort by Padmanabhan et al. (2007), who developed a new calibration algorithm that simultaneously solves for the calibration parameters and relative stellar fluxes using overlapping SDSS observations (the so-called *übercalibration* method). The algorithm decouples the problem of “relative” calibrations (i.e. producing an internally consistent system), from that of “absolute” calibrations (i.e. tying the internal system to a physical flux scale): the absolute calibration is reduced to determining a few numbers for the entire survey. Here we also decouple “relative” and “absolute” calibrations and use overlapping observations. The main difference between their work and this paper is that they are concerned about calibrating the entire SDSS survey ($\sim 8500 \text{ deg}^2$; most of the surveyed area has at most two overlapping observations), while we concentrate here on a much smaller area ($\sim 300 \text{ deg}^2$) with an average of ten overlapping observations. We also determine flatfield corrections (relative to the “standard” survey reductions) using different methods: Padmanabhan et al. minimize errors in relative photometry of multiply observed stars, while we require that the stellar locus remains fixed in multi-dimensional color space. An advantage of the catalog presented here is better averaging of various photometric errors thanks to a larger number of observations, which comes at the expense of a much smaller cataloged area. It is encouraging that the results of these two complementary approaches agree in the regions of sky common to both catalogs at the claimed level of accuracy ($\sim 1\%$).

Additional motivation for the analysis of repeated scans and their impact on photometric accuracy comes from upcoming large-scale optical surveys such as the Dark Energy Survey (Flaugher et al. 2007), Pan-STARRS (Kaiser 2002) and the Large Synoptic Survey Telescope (Tyson 2002, LSST hereafter). For example, the LSST science requirements document¹ calls for a photometric system that is internally consistent across the sky at the 1% level. The SDSS Stripe 82 repeated scans can be used to gauge the plausibility of delivering such a system.

¹Available from http://www.lsst.org/Science/lsst_baseline.shtml

We describe the construction and testing of a standard star catalog in §2, and illustrate its several use cases in §3. We discuss our results in §4.

2. The Construction of SDSS Stripe 82 Standard Star Catalog

2.1. Overview of SDSS imaging data

SDSS is using a dedicated 2.5m telescope (Gunn et al. 2006) to provide homogeneous and deep ($r < 22.5$) photometry in five bandpasses (Fukugita et al. 1996; Gunn et al. 1998, 2006; Smith et al. 2002; Hogg et al. 2002) repeatable to 0.02 mag (root-mean-square scatter, hereafter rms, for sources not limited by photon statistics, Ivezić et al. 2003) and with a zeropoint uncertainty of ~ 0.02 -0.03 (Ivezić et al. 2004a). The survey sky coverage of close to $\sim 10,000$ deg² in the Northern Galactic Cap, and ~ 300 deg² in the Southern Galactic Hemisphere, will result in photometric measurements for well over 100 million stars and a similar number of galaxies². Astrometric positions are accurate to better than 0.1 arcsec per coordinate (rms) for sources with $r < 20.5^m$ (Pier et al. 2003), and the morphological information from the images allows reliable star-galaxy separation to $r \sim 21.5^m$ (Lupton et al. 2002, Scranton et al. 2002).

Data from the imaging camera (thirty photometric, twelve astrometric, and two focus CCDs, Gunn et al. 1998) are collected in drift scan mode. The images that correspond to the same sky location in each of the five photometric bandpasses (these five images are collected over ~ 5 minutes, with 54 sec for each exposure) are grouped together for simultaneous processing as a field. A field is defined as a 36 seconds (1361 pixels, or 9 arcmin, see Stoughton et al. 2002) long and 2048 pixels wide (13 arcmin) stretch of drift-scanning data from a single column of CCDs (sometimes called a scanline, for more details please see Stoughton et al. 2002; Abazajian et al. 2003, 2004, 2005; Adelman-McCarthy et al. 2006). Each of the six scanlines (called together a strip) is 13 arcmin wide. The twelve interleaved scanlines (or two strips) are called a stripe ($\sim 2.5^\circ$ wide).

2.2. The photometric calibration of SDSS imaging data

SDSS 2.5m imaging data are photometrically calibrated using a network of calibration stars obtained in $1520 \times 41.5 \times 41.5$ arcmin² transfer fields, called secondary patches. These

²The recent Data Release 5 (Adelman-McCarthy et al. 2007, in prep) lists photometric data for 215 million unique objects observed in 8000 deg² of sky; see <http://www.sdss.org/dr5/>.

patches are positioned throughout the survey area and are calibrated using a primary standard star network of 158 stars distributed around the Northern sky (so-called USNO standards, Smith et al. 2002). The primary standard star network is tied to an absolute flux system by the single F0 subdwarf star BD+17°4708, whose absolute fluxes in SDSS filters are taken from Fukugita et al. (1996). The secondary patches are grouped into sets of four, and are observed by the Photometric Telescope (hereafter PT; Tucker et al. 2006) in parallel with observations of the primary standards. A set of four patches spans all 12 scanlines of a survey stripe along the width of the stripe, and the sets are spaced along the length of a stripe at roughly 15 degree intervals, which corresponds to an hour of scanning at the sidereal rate.

SDSS 2.5m magnitudes are reported on the “natural system” of the 2.5m telescope defined by the photon-weighted effective wavelengths of each combination of SDSS filter, CCD response, telescope transmission, and atmospheric transmission at a reference airmass of 1.3 as measured at APO³. The magnitudes are referred to as the *ugriz* system (which differs from the “primed” system, $u'g'r'i'z'$, that is defined by the USNO standards⁴). The reported magnitudes⁵ are corrected for the atmospheric extinction (using simultaneous observations of standard stars by the PT) and thus correspond to measurements at the top of the atmosphere⁶ (except for the fact that the atmosphere has an impact on the wavelength dependence of the photometric system response). The magnitudes are reported on the AB system (Oke & Gunn 1983) defined such that an object with a specific flux of $F_\nu=3631$ Jy has $m = 0$ (i.e. an object with $F_\nu=\text{const.}$ has an AB magnitude equal to the Johnson V magnitude at all wavelengths). In summary, given a specific flux of an object *at the top* of the atmosphere, $F_\nu(\lambda)$, the reported SDSS 2.5m magnitude in a given band, $b=(u, g, r, i, z)$, corresponds to (modulo random and systematic errors, which will be discussed later)

$$m = -2.5 \log_{10} \left(\frac{F_b}{3631 \text{ Jy}} \right), \quad (1)$$

³Transmission curves for the SDSS 2.5m photometric system are available at <http://www.sdss.org/dr5/instruments/imager>

⁴For subtle effects that led to this distinction, please see Stoughton et al. (2002), Smith et al. (2002), and <http://www.sdss.org/dr5/algorithms/fluxcal.html>.

⁵SDSS uses a modified magnitude system (Lupton, Szalay & Gunn 1999), which is virtually identical to the standard astronomical Pogson magnitude system at high signal-to-noise ratios relevant here.

⁶The same atmospheric extinction correction is applied irrespective of the source color; the systematic errors this introduces are probably less than 1% for all but objects of the most extreme colors.

where

$$F_b = \int F_\nu(\lambda) \phi_b(\lambda) d\lambda. \quad (2)$$

Here, $\phi_b(\lambda)$ is the normalized system response for the given band,

$$\phi_b(\lambda) = \frac{\lambda^{-1} S_b(\lambda)}{\int \lambda^{-1} S_b(\lambda) d\lambda}, \quad (3)$$

with the overall atmosphere + system throughput, $S_b(\lambda)$, available from the website given above ($\phi_b(\lambda)$ for the SDSS system are shown in Figure 6, see also § 2.5.2). We reiterate that the *normalization* of reported magnitudes corresponds to a source at the top of the atmosphere, while the throughput $\phi_b(\lambda)$ includes the transmission of a standard atmosphere at a fiducial airmass of 1.3. Note also that it is only the *shape* of $S_b(\lambda)$, and not its overall normalization, that needs to be known to compute expected SDSS magnitudes of a source with given $F_\nu(\lambda)$. That is, the SDSS photometric system is fully *defined* by the five *dimensionless* functions $\phi_b(\lambda)$ (by definition, $\int \phi_b d\lambda = 1$, see eq. 3). In reality, for each *ugriz* band there are six devices in the SDSS camera (Gunn et al. 1998) whose ϕ_b are slightly different (see § 2.5.2).

The quality of SDSS photometry stands out among available large-area optical sky surveys (Ivezić et al. 2003, 2004a; Sesar et al. 2006). Nevertheless, the achieved accuracy is occasionally worse than the nominal 0.02-0.03 mag (root-mean-square scatter for sources not limited by photon statistics). Typical causes of substandard photometry include an incorrectly modeled point spread function (PSF; usually due to fast variations of atmospheric seeing, or lack of a sufficient number of the isolated bright stars needed for modeling the PSF), unrecognized changes in atmospheric transparency, errors in photometric zeropoint calibration, effects of crowded fields at low Galactic latitudes, an undersampled PSF in excellent seeing conditions ($\lesssim 0.8$ arcsec; the pixel size is 0.4 arcsec), incorrect flatfield or bias vectors, scattered light erroneously included in flatfield, etc. Such effects can conspire to increase the photometric errors to levels as high as 0.05 mag (with a frequency, at that error level, of roughly one field per thousand). However, when multiple scans of the same sky region are available, many of these errors can be minimized by properly averaging photometric measurements.

2.3. The Choice of Cataloged Magnitudes

The SDSS photometric pipeline (*photo*, Lupton et al. 2002) measures several types of magnitudes, including aperture, PSF, and model magnitudes. Here we briefly describe

each type of magnitude (for more details see Stoughton et al. 2002, and the SDSS website www.sdss.org) and justify the choice of PSF magnitudes for catalog construction.

2.3.1. *Aperture magnitudes*

Aperture magnitudes computed by *photo* are based on the flux contained within the aperture with a radius of 7.43 arcsec. While an aperture magnitude is the most robust flux estimate at the bright end (because it is essentially seeing independent), these magnitudes do not have good noise properties at the faint end where sky noise dominates (e.g. for a given maximum photometric error, PSF magnitudes reach 1–1.5 mag fainter than do aperture magnitudes). In order to improve the depth of the standard star catalog, we opt not to use aperture magnitudes, except for quality tests at the bright end.

2.3.2. *Point spread function magnitudes*

The point spread function (PSF) flux is computed using the PSF as a weighting function. While this flux is optimal for faint point sources (in particular, it is vastly superior to aperture photometry at the faint end), it is also sensitive to inaccurate PSF modeling as a function of position and time. Even in the absence of atmospheric variations, the SDSS telescope and camera optics deliver images whose FWHMs vary by up to 15% from one side of a CCD to the other; the worst effects are seen in the chips farthest from the optical axis. Moreover, since the atmospheric seeing varies with time, the delivered image quality is a complex two-dimensional function even on the scale of a single frame. Without accounting for this spatial variation, the PSF photometry would have errors up to 0.10–0.15 mag. The description of the PSF is also critical for star-galaxy separation and for unbiased measures of the shapes of nonstellar objects.

The SDSS imaging PSF is modeled heuristically in each band and each camera column using a Karhunen-Loève (KL) transform (Lupton et al. 2002). Using stars brighter than roughly 20th magnitude, the PSF from a series of five frames is expanded into eigenimages and the first three terms are retained. The variation of these coefficients is then fit up to a second order polynomial in each chip coordinate. The failure of this KL expansion, typically due to insufficient number of stars, or exceedingly complex PSF, results in occasional problems with PSF photometry. The main failure mode is inaccurate determination of aperture corrections which statistically tie PSF magnitudes to aperture magnitudes using bright stars.

2.3.3. Model magnitudes

Just as the PSF magnitudes are optimal measures of the fluxes of stars, the optimal measure of the flux of a galaxy uses a matched galaxy model. With this in mind, the photometric pipeline fits two models to the two-dimensional image of each object in each band: a pure deVaucouleurs profile and a pure exponential profile⁷. Because the models are convolved with a double-Gaussian fit to the PSF, the seeing effects are accounted for. Aperture corrections are applied to make these model magnitudes equal the PSF magnitudes in the case of an unresolved object.

2.3.4. The choice of magnitudes for the standard star catalog

A comparison between aperture, PSF and model magnitudes for unresolved sources is done automatically for every SDSS observing run (*runQA* pipeline, Ivezić et al. 2004a). An analysis of over 200 runs indicate that model magnitudes are more robust than PSF magnitudes: PSF magnitudes show systematic offsets of 0.05 mag from aperture magnitudes three times more often than do model magnitudes (roughly once per thousand fields), as model fits have more degrees of freedom. On the other hand, an analysis of repeated scans indicates that estimates of photometric errors by the photometric pipeline are more accurate for PSF magnitudes (agreeing at the 10% level with the measured values, see Ivezić et al. 2003; Scranton et al. 2005) than for model magnitudes (which are smaller than the measured values by typically 30-50%). Because the rejection of likely variable sources, which relies on accurate photometric error estimates, is an important step in the construction of the standard star catalog (see below), we choose to use PSF magnitudes to construct the catalog.

2.4. Catalog Construction

Using 58 SDSS-I runs from stripe 82 (approximately $20^{\text{h}} < \alpha_{J2000} < 04^{\text{h}}$ and $|\delta_{J2000}| < 1.266^\circ$, but not all runs extend over the entire right ascension range) obtained in mostly photometric conditions (as indicated by the PT calibration residuals, infrared cloud camera⁸, and tests performed by the *runQA* pipeline), candidate standard stars from each run are selected by requiring

⁷For more details see <http://www.sdss.org/dr5/algorithms/photometry.html>

⁸For more details about the camera see http://hoggpt.apo.nmsu.edu/irsc/irsc_doc and Hogg et al. (2002).

1. that objects are classified as STAR (based on the difference between model and PSF magnitudes); this morphological classification really means unresolved (point) sources (e.g. quasars are also included),
2. that they have quoted photometric errors in the PSF magnitude (as computed by the photometric pipeline) smaller than 0.05 mag in at least one band, and
3. that the processing flags BRIGHT, SATUR, BLENDED, or EDGE are not set in any band⁹.

These criteria select unsaturated point sources with sufficiently high signal-to-noise ratio per single observation to approach final photometric errors of 0.02 mag or smaller.

After matching all detections of a single source across runs (using a 1 arcsec matching radius), various photometric statistics such as unweighted mean, median, their standard errors, root-mean-square scatter, number of observations, and χ^2 per degree of freedom, are computed for magnitudes in each band. We use errors reported by the photometric pipeline to compute χ^2 and note that systematic errors common to all runs do not contribute to its value. This initial catalog of multi-epoch observations includes 1.4 million point sources with at least 4 observations in each of the g , r and i bands. The median number of observations per source and band is 10, and the total number of photometric measurements is ~ 57 million.

The distributions of the median magnitudes, their standard errors, χ^2 and the number of observations for a subset of these sources are shown in Figure 1. The random errors in the median magnitude (computed as $0.928 \cdot \text{IQR} / \sqrt{N - 1}$, where IQR is the 25%–75% interquartile range of the individual measurement distribution and N is the number of measurements; note that the error of the median for a Gaussian distribution is 25% larger than the error of the mean, Lupton 1993) are below 0.01 mag at the bright end. These errors are reliably computed by the photometric pipeline, as indicated by the χ^2 distributions. The distributions of these sources in color-magnitude and color-color diagrams, constructed using median magnitudes, are shown in Figure 2. For a detailed interpretation of these diagrams, please see Lenz et al. (1998), Fan (1999), Finlator et al. (2000), Helmi et al. (2003), and Ivezić et al. 2006. As evident, the sample is dominated by stars.

⁹For more details about processing flags see <http://www.sdss.org/dr5/products/catalogs/flags.html> and Stoughton et al. (2002).

2.4.1. Selection of Candidate Standard Stars

Adopted candidate standard stars must have at least 4 observations and, to avoid variable sources, χ^2 less than 3 in the *gri* bands (the same requirements are later applied in the *u* and *z* bands when using the catalog for calibration, as we discuss further below). We also limit the right ascension to the range from 20h 34m to 4h 00m, which provides a simple areal definition (together with $|\delta_{J2000}| < 1.266^\circ$) of a 282 deg^2 large rectangular region, while excluding only a negligible fraction of stars. With the final condition that the standard error for the mean magnitude in the *r* band is smaller than 0.05 mag, these requirements result in a catalog with slightly over a million sources (1,006,849) with 42 million photometric measurements. Of those, 563,908 have a random error for the median magnitude in the *r* band smaller than 0.01 mag, and for 405,954 stars this is true in all three of the *gri* bands. Subsets of 92,905 and 290,299 stars satisfy these requirements in the *ugri* and *griz* bands, and 91,853 stars satisfy this in all five bands. The distributions of candidate standard stars that satisfy the above selection criteria in all five bands in color-magnitude and color-color diagrams are shown in Figure 3.

For comparison, the distribution of sources that were rejected as variable (χ^2 greater than 3 in at least one of the *gri* bands) in color-magnitude and color-color diagrams is shown in Figure 4. As evident from a comparison with Figure 3, the distribution of variable sources in color-color diagrams is markedly different from that of non-variable sources. It is especially striking how low-redshift ($z < 2.2$) quasars are easily detected by their variability (for more details see Ivezić et al. 2004b). However, it is fairly certain that not all variable sources are recognized as such because of the limited number of repeated observations (~ 10). For example, an eclipsing binary with much shorter eclipse duration than the orbital period could easily escape detection. Analysis of the variable subsample is presented in a companion paper (Sesar et al. 2007, in prep.).

The sky density of all the sources and those selected as non-variable are shown in Figure 5. At high Galactic latitudes ($|b| \sim 60^\circ$) the fraction of candidate standard stars sources is $\sim 80\%$.

2.5. Systematic Photometric Errors

Photometric errors computed by the photometric pipeline provide a good estimate of random errors in SDSS photometry, as demonstrated by the χ^2 distributions shown in Figure 1. However, the measurements are also subject to systematic errors such as spatial dependence of the internal zeropoints (calibration errors), and the overall deviations of the

internal SDSS zeropoints from an AB magnitude scale. Formally, the true AB magnitude of an object (defined by eq.1) in a given band, m_{true} , can be expressed as

$$m_{true} = m_{cat} + \delta_m(\text{RA}, \text{Dec}) + \Delta_m, \quad (4)$$

where m_{cat} is the cataloged magnitude, $\delta_m(\text{RA}, \text{Dec})$ describes the spatial variation of the internal zeropoint error around Δ_m (thus the average of δ_m over the cataloged area is 0 by construction), and Δ_m is the overall (spatially independent) deviation of the internal SDSS system from a perfect AB system (the five values Δ_m are equal for all the cataloged objects). Here we ignore systematic effects, e.g., device non-linearity and bandpass variations between different camera columns, which depend on individual source properties such as brightness and colors (but see §2.5.2 below).

The spatial variation of the internal zeropoint error can be separated into *color* errors, relative to a fiducial band, say r , and an overall “gray” error (e.g. unrecognized temporal changes in atmospheric transparency due to gray clouds)

$$\delta_m(\text{RA}, \text{Dec}) = \delta_r(\text{RA}, \text{Dec}) + \delta_{mr}(\text{RA}, \text{Dec}). \quad (5)$$

Below we discuss methods for estimating both the “gray” error $\delta_r(\text{RA}, \text{Dec})$ and the color errors $\delta_{mr}(\text{RA}, \text{Dec})$.

The deviation of the internal SDSS system from a perfect AB system, Δ_m , can also be expressed relative to the fiducial r band

$$\Delta_m = \Delta_r + \Delta_{mr}. \quad (6)$$

The motivation for this separation is twofold. First, Δ_{mr} can be constrained by considering the colors (spectral energy distributions) of objects, independently from the overall flux scale (this can be done using both external observations and models). Second, it is difficult to find a science result that crucially depends on knowing the “gray scale” offset, Δ_r , at the 1-2% level. On the other hand, knowing the “band-to-band” offsets, Δ_{mr} , with such an accuracy is important for many applications (e.g., photometric redshifts of galaxies, type Ia supernovae cosmology, testing of stellar and galaxy models).

Fitting SDSS spectra of hot white dwarfs to models, Eisenstein et al. (2006) determined the AB color corrections Δ_{mr} to be -0.04 , 0.00 , -0.015 and -0.015 mag for $m = ugiz$, respectively, with an uncertainty of ~ 0.01 - 0.02 mag. It may be possible to determine these corrections with an uncertainty of ~ 0.01 mag, and such efforts are in progress (J. Marriner, priv. comm.).

The overall “gray” flux scale calibration error, Δ_r , is determined by the accuracy of the absolute flux calibration of fundamental standard BD+17°4708 (Fukugita et al. 1996),

the accuracy of tying the primary standard star network to BD+17°4708, the accuracy of transferring the primary standard star network to the secondary standard star network, and the accuracy of the calibration of the survey imaging data using the secondary standard star network. Given these numerous sources of error, it seems unlikely that $\Delta_r < 0.02$ mag. On the other hand, formal analysis of all the error contributions, as well as a direct comparison to HST observations of hot white dwarfs (Eisenstein et al. 2006), suggest that Δ_r does not exceed 0.05 mag. Note, however, that all these uncertainties in the definition and transfer of the standard star network become moot if one accepts that

1. Δ_r does not need to be known exquisitely well for most scientific applications. Even if it does, this is just *a single number* that modifies the cataloged photometry for all the sources and all the bands in the same fashion.
2. Uncertainties in the determination of Δ_{mr} are of the order 0.01 mag.
3. $\delta_m(\text{RA}, \text{Dec})$ can be constrained, or corrected for, at the 0.01 mag level.

In other words, the band-to-band calibration can be fixed by adopting Δ_{mr} , determining and correcting for $\delta_m(\text{RA}, \text{Dec})$ guarantees internal consistency, and the only remaining relatively free parameter is Δ_r . Such a system is then *no longer defined by a set of celestial standards but rather by the functions ϕ_b* . The catalog presented here is one realization of such a photometric system.

2.5.1. Determination of $\delta_m(\text{RA}, \text{Dec})$

We now proceed to describe methods for constraining $\delta_m(\text{RA}, \text{Dec})$. The region covered by the SDSS Stripe 82 is an elongated rectangle with an aspect ratio of 1:50, and with the long side parallel to the Celestial Equator. Because of this large aspect ratio, and because different effects contribute to the RA and Dec dependences of δ_m , we assume that it can be expressed as a sum of independent functions of RA or Dec, respectively

$$\delta_m(\text{RA}, \text{Dec}) = \delta_m^{ff}(\text{Dec}) + \delta_m^{ext}(\text{RA}), \quad (7)$$

with $\langle \delta_m^{ff}(\text{Dec}) \rangle_{\text{RA}} = 0$ and $\langle \delta_m^{ext}(\text{RA}) \rangle_{\text{Dec}} = 0$, where $\langle \delta \rangle_x$ denotes the average of δ over direction x .

The first term, $\delta_m^{ff}(\text{Dec})$, is dominated by the errors in the flatfield vectors (for drift scanning, flatfield corrections are one-dimensional). The flatfield determination for SDSS

was difficult due to scattered light¹⁰ and there are probably systematic errors in the stellar photometry at the 0.01 mag level in the *griz* bands and the 0.02 mag level in the *u* band (perhaps somewhat larger at the edge of the imaging camera), as we will demonstrate below. Since these systematic errors do *not* cancel when averaging many observing runs (because most stars are always observed by the same CCD and fall on roughly the same position within the CCD), $\delta_m^{ff}(\text{Dec})$ could be as large as $\sim 0.01 - 0.02$ mag on spatial scales much smaller than the chip width of 13 arcmin.

The second term, $\delta_{mr}^{ext}(\text{RA})$, is dominated by unrecognized fast variations of atmospheric extinction (e.g. due to cirrus), because for each observing run only a single zeropoint per CCD is determined¹¹. While such variations are uncorrelated for different runs, it is possible that they do not average out fully at the 1% level.

2.5.2. The six *ugriz* photometric systems

Before we describe methods for determining $\delta_m(\text{RA}, \text{Dec})$, we address the bandpass differences between the six camera columns. The bandpasses had been measured for each CCD using a monochromator (M. Doi et al. 2007, in prep.) and found not to be identical, as shown in Figure 6. These differences between the bandpasses induce color term errors in the reported SDSS photometry because the magnitudes of calibration stars obtained by the PT are transformed to the 2.5m system using a single set of color terms¹². In other words, the color difference between a blue star and a red star depends on which camera column the stars fall on: *at the $\sim 1\%$ accuracy level discussed here, there are six SDSS *ugriz* systems.*

We used the measured response curves to generate synthetic *ugriz* photometry corresponding to six camera columns (via eq.1) for 175 stars from the Gunn-Stryker atlas (1983). The differences between the predicted magnitudes for each camera column and the values generated with the response curves which define the SDSS system¹³ represent photometric corrections due to bandpass differences. These corrections may be as large as 0.02 mag for

¹⁰For details please see <http://www.sdss.org/dr5/algorithms/flatfield.html> and Stoughton et al. (2002).

¹¹Although not relevant for equatorial runs discussed here, slow change of atmospheric extinction due to varying airmass is accounted for; the response of the telescope and CCDs is stable at the $<1\%$ level on single-night timescales.

¹²See http://www.sdss.org/dr5/algorithms/jeg_photometric_eq_dr1.html

¹³Transmission curves for the SDSS 2.5m photometric system are available at <http://www.sdss.org/dr5/instruments/imager>

the reddest stars, but fortunately admit simple linear fits as a function of color ($u - g$ for the u band, $g - r$ for g and r , and $r - i$ for i and z). The u band is the only one where piecewise fits are required (in the range $0.7 < u - g < 1.3$, the $g - r$ color provides a better fit than the $u - g$ color). We have applied these best-fit corrections to all sources in the catalog. The median and rms scatter for the distributions of corrections evaluated for all stars, and for each color and camera column combination, are listed in Table 1.

The bandpass differences have the largest impact on the $i - z$ color of red sources. The color term errors result in a rotation of the stellar locus in the $i - z$ vs. $r - i$ color-color diagram (see the bottom right panel in Figure 2), and we utilize this fact to demonstrate the improvement in photometry due to applied corrections. We use the mean position of the stellar locus to “predict” the $i - z$ color from the measured $r - i$ color, and compute the difference between predicted and measured $i - z$ colors separately for blue ($0.1 < r - i < 0.2$) and red ($0.8 < r - i < 1.4$) stars, and in small bins of declination (cross-scan direction). The difference of these residuals (blue vs. red stars) effectively measures the locus position angle and is not sensitive to photometric zeropoint errors and flatfield errors (which can only induce locus shifts that have no effect on this test because they cancel out).

The top panel in Figure 7 shows the median $i - z$ residuals before applying corrections for different transmission curves, and the bottom panel shows results based on corrected photometry. The rms scatter decreases from 9 millimag to 3 millimag after applying the corrections. The remaining deviations of residuals from zero could be due to the fact that we have not corrected for dependence of the flatfields on source color (measurements of this dependence are not available). Because this is currently the only available SDSS catalog with photometry corrected for bandpass differences, it *effectively* represents a practical definition of the SDSS photometric system (i.e. it provides photometry for real sources on the sky; the system is formally defined by ϕ_b , of course).

2.5.3. Other Sources of Systematic Errors

The non-linearity of the detectors (as a function of source brightness) has also been measured *in situ* by Doi et al. and found to be at most a couple of percent effect over the relevant dynamic range¹⁴. These corrections are determined with a sufficient accuracy (<5 millimag impact on photometry) and are already implemented in the photometric pipeline (i.e. before performing photometric calibration).

¹⁴For details see <http://www.sdss.org/dr5/instruments/imager/nonlinearity.html>

Similarly to the camera column-to-column bandpass differences, variations in the wavelength dependence of atmospheric transmissivity can also induce systematic errors that depend on source colors. Assuming a standard atmosphere, we find using synthetic photometry for stars from the Gunn-Stryker atlas that this effect can induce offsets of up to ~ 0.01 mag for the $u-g$ and $g-r$ colors when airmass is varied by 0.3 from its fiducial value of 1.3. However, because all stripe 82 data are obtained at the same airmass, this effect is not relevant for the catalog discussed here. At least in principle, similar, and potentially larger, errors could be induced even at a constant airmass if the wavelength dependence of atmospheric transmissivity is significantly different from the assumed standard atmosphere. Given that such errors would probably average out, and that there are no available measurements of the wavelength dependence of atmospheric transmissivity¹⁵ for SDSS data considered here, we ignore this effect hereafter.

2.6. Determination of Flatfield Corrections

We use two methods based on SDSS data to constrain $\delta_m(\text{RA}, \text{Dec})$: a direct comparison with the secondary standard star network (§2.6.2) and a method based on stellar colors (§2.6.1). Each of these methods has its advantages and disadvantages. We perform the tests of the final catalog quality using a method based on the photometric redshift relation for galaxies (§2.7.2), and also compare the SDSS photometry to an independent set of standards provided by Stetson (2000, 2005) in §2.7.3.

A determination of the $\delta_m(\text{RA}, \text{Dec})$ error from a direct comparison with the secondary standard star network (hereafter PT comparison) might be considered as the best method *a priori*. However, it is quite possible that the secondary standard star network itself, off of which this catalog is calibrated, may induce a spatial variation of the photometric zeropoints at the 0.01 mag level (Smith et al. 2002). In addition, there are not enough stars to constrain $\delta_m^{ff}(\text{Dec})$ with sufficient spatial resolution (say, at least ~ 100 pixels, or $\sim 0.01^\circ$). For example, there are $\sim 20,000$ secondary standards from Stripe 82 in the averaged catalog that are not saturated in the gri bands in the 2.5m scans, and have PT errors smaller than 0.03 mag ($\sim 8,000$ stars are useable in the z band, and only $\sim 3,000$ in the u band). If these stars are

¹⁵Some handle on the stability of the wavelength dependence of atmospheric transmissivity can be obtained by studying first-order extinction coefficients determined by the photometric calibration pipeline. They show a cyclic variation during the year, with an rms scatter of residuals around the mean relation of 0.01 mag. The amplitude of the yearly variation of the r band extinction coefficient is $\sim 20\%$ about the mean value, and the wavelength dependence of the variation appears consistent with the addition of a gray opacity source during summer months.

binned in the declination direction every 0.01° (250 90-pixels wide bins), δ_m^{ff} in each bin can be constrained to about ~ 0.005 mag (0.01 mag in the u band). This is barely sufficient in the gri bands, and cannot provide satisfactory constraints on the flatfielding errors in the u band (where unfortunately these errors are the largest). Similarly, $\delta_m^{ext}(\text{RA})$ can be constrained in 0.5° wide right ascension bins with a similar accuracy, but the secondary standard stars are not uniformly distributed in right ascension. For these reasons, we combine the PT comparison with the stellar locus method to determine flatfield corrections.

2.6.1. Color corrections from the stellar locus method

The stellar distribution in color-color space at high Galactic latitudes¹⁶ ($|b| > 30$) is remarkably uniform at the faint flux levels probed by SDSS, as discussed in detail by Ivezić et al. (2004a). Systematic photometric errors, other than an overall gray error, manifest themselves as shifts in the position of the stellar locus that can be tracked using the four principal colors ($swxy$) defined by Ivezić et al. (2004a). These colors are linear combinations of magnitudes,

$$P_2 = A u + B g + C r + D i + E z + F, \quad (8)$$

where $P_2 = s, w, x, y$, and measure the distance from the center of the locus in various two-dimensional projections of the four-dimensional stellar color distributions (s : perpendicular to the blue part of the locus in the $g-r$ vs. $u-g$ plane, w : perpendicular to the blue part in the $r-i$ vs. $g-r$ plane, x : perpendicular to the red part, with $g-r \sim 1.4$, in the $r-i$ vs. $g-r$ plane, and y : perpendicular to the locus in the $i-z$ vs. $r-i$ plane). The matrix of coefficients $A-F$ is listed in Table 2 (for more details see Ivezić et al. 2004a). Of course, the measurements must be corrected for the effects of interstellar dust extinction; we use maps provided by Schlegel, Finkbeiner & Davis (1998, hereafter SFD98). The properties of two of these colors (s and w) are illustrated in Figure 8.

The fact that the median principal colors are close to zero shows that the averaging procedure did not induce any shifts in zeropoints compared to the average of 291 SDSS runs which were used to define the principal colors (Ivezić et al. 2004a). The same conclusion is reached by comparing the averaged photometry with the secondary standard star network: the median photometric residuals at the so-called crossing colors¹⁷ are 4, 6, 3, 2 and 2

¹⁶At low Galactic latitudes several effects, discussed below, prevent the use of this method for calibration purposes.

¹⁷Crossing colors are roughly the median colors of the observed stellar population, for details see http://www.sdss.org/dr5/algorithms/jeg_photometric_eq_dr1.html

millimag in the *ugriz* bands, respectively. Yet another test is a direct comparison of averaged photometry with single-epoch photometry. Using the SDSS Data Release 5 photometry, we find that the largest median magnitude difference between the two sets is 2 millimag in the *u* band.

It is noteworthy that the widths of the principal color distributions (i.e. the thickness of the stellar locus) constructed with averaged photometry are much smaller than when using single-epoch data (see the bottom four panels in Figure 8). Indeed, all four principal color distributions are "resolved" using this high quality photometry (see the fifth column in Table 3).

Because the intrinsic widths of the principal color distributions are so small, principal colors can be used to efficiently track local calibration problems using a small number of stars, allowing a high spatial resolution. That is, we require that the locus not move in the multi-dimensional color space. In practice, the deviations of the principal colors from 0 can be inverted, using an appropriate closure relation (see the next section), to yield flatfield corrections (Ivezić et al. 2004a). With bins 0.01° wide in the declination direction, or 1° wide in the right ascension direction, the flatfield corrections can be determined with an accuracy of 5 millimag, or better.

2.6.2. *Gray corrections from the comparison with secondary standard star network*

The main advantage of the stellar locus method is that it can constrain δ_{mr} with high spatial resolution. However, it is insensitive to gray errors, parametrized by δ_r (e.g. an overall gradient of photometric zeropoints in the declination direction that is the same in all five bands would have no effect on stellar colors). On the other hand, the PT comparison can constrain δ_r , but it does not provide enough spatial resolution to derive flatfield corrections, especially in the *u* and *z* bands. Therefore, we combine these two methods to derive flatfield corrections $\delta_m^{ff}(\text{Dec})$.

The median differences between the averaged 2.5m photometry and PT photometry for secondary standard stars in the *gri* bands are shown in the top panel in Figure 9. The median differences are computed for 0.01° wide bins, and then smoothed by a triangular filter (y_i is replaced by $0.25 * (y_{i-1} + 2y_i + y_{i+1})$). The residuals in all three bands display similar behavior and imply about 0.02 peak-to-peak variation between the center and edges on each CCD (resulting in about 6 millimag rms contribution to the overall errors), as well as an overall 0.01-0.02 mag tilt. These systematic errors may be due to imperfect flatfield vectors used to reduce the data, incorrectly determined scattered light correction (the two

are somewhat coupled in the data reduction procedures), or problems in PT itself (such as the PT flatfield).

At face value, these residuals could be used to correct the averaged 2.5m photometry in each band (*gri*) separately. However, doing so introduces noise in stellar principal colors of about 5 millimag (rms) and suggests that the differences in photometric residuals between the three bands are dominated by PT measurement noise. On the other hand, the 2.5m vs. PT residuals do contain information about “gray” errors that *cannot* be determined using stellar locus. Hence, we take the *mean* value of the 2.5m vs. PT residuals in the *gri* bands to represent the δ_r flatfield correction, and apply it to the averaged 2.5m photometry in the *r* band. The applied *r* band correction is shown in the second panel in Figure 9 and has an rms scatter of 7 millimag (for 250 bins), with the largest correction less than 0.02 mag.

In the second step, we use the stellar locus to derive the δ_{mr} corrections in each band (*ugiz*). The derivation of these corrections is essentially identical to the procedure described by Ivezić et al. (2004a). Also, together with a PT-based δ_r correction, this is essentially the same method as used to derive flatfield corrections for the whole SDSS survey¹⁸. In particular, we used here the same closure relation (stellar locus method gives four equations for five unknowns), that is based on averaged 2.5m vs. PT residuals in the *gri* bands. The resulting flatfield corrections, δ_{mr} , in the *ugiz* bands are shown in the third and fourth panels in Figure 9 and summarized in Table 4.

Due to low stellar counts and the strongest scattered light, the *u* band correction is expected to have the largest noise (~ 5 -10 millimag), which is consistent with the observed behavior. It is thus likely that some of the variation on scales of $\sim 0.01^\circ$ is not real. On the other hand, it could be argued that systematic errors could actually be much larger on even smaller spatial scales, but get averaged out in 90 pixel wide bins. However, in addition to not having a reason to believe in such high spatial frequency effects (e.g. the sky background does not show any evidence for them), no additional scatter, except the expected statistical noise, is observed when the bin size is decreased by a factor of 4.

Last but not least, it is important to emphasize that these corrections are *not* setting photometric zeropoints, but only correcting for variations in response across each CCD. As discussed above, the AB photometric zeropoints, relative to the fiducial *r* band, *are effectively set by adopting values for Δ_{mr} .*

¹⁸For details see <http://www.sdss.org/dr5/algorithms/flatfield.html>.

2.7. Tests of Catalog Quality

2.7.1. The internal tests

At least in principle, the same methods used to derive $\delta_m^{ff}(\text{Dec})$ could be used to derive $\delta_m^{ext}(\text{RA})$. However, in practice this is not possible for at least two reasons: first, the right ascension distribution of secondary standard stars is not as uniform as their declination distribution, and second, the assumption of the constancy of the stellar locus in color space is invalid along the “long” scan direction (discussed below). For these reasons, we only use the PT comparison and stellar locus methods to estimate the level of internal zeropoint variations with RA, and do *not* correct the data. In the next section, we will also use another method, based on galaxy colors, as an independent test of catalog integrity.

Figure 10 shows the median principal colors in bins of right ascension. As evident, the principal colors are close to zero for the right ascension in the range $-25^\circ < \text{RA} < 40^\circ$, but outside this range deviate significantly from zero. This does not necessarily indicate problems with photometric calibration, because the stellar locus method is expected to fail at low Galactic latitudes due to several reasons. First, the mean metallicity of stars increases at low Galactic latitudes and this change may affect the s and w colors. Second, at low latitudes red dwarfs are not behind the entire dust screen measured by the SFD98 maps (see Jurić et al. 2006 for a discussion of this point), and thus the x color will be biased blue (i.e. the colors of red dwarfs are over-corrected for the ISM reddening). And third, at low latitudes the dust column increases fast (see Figure 11) and even small errors in the *assumed* wavelength dependence of the dust extinction, or the extinction itself as given by the SFD98 maps, will have noticeable effects on principal colors. For these reasons, it seems plausible that the deviations seen in Figure 10 are *not* dominated by zeropoint errors.

This conclusion is supported by the direct comparison of the averaged and PT photometry (Figure 11). For example, the largest median photometric residual between the averaged catalog and PT observations in the u band is ~ 0.02 mag (see Table 5), which is much smaller than the 0.1 mag discrepancy implied by the stellar locus method.

Table 5 shows that the rms scatter of median photometric residuals (evaluated in 2° wide bins in the right ascension direction) between the averaged catalog and PT observations is < 0.01 mag in all five bands. Some of that scatter must come from the PT data itself, and thus the true scatter of photometric zeropoints in the averaged catalog is probably even smaller than that listed in Table 5. In addition, Table 5 shows that the averaged catalog and PT measurements are on the same system to within a few millimags (using the recommended photometric transformations between the two telescopes listed at the SDSS website, see Section 2.2).

We have also compared the catalog presented here to photometric reductions described by Padmanabhan et al. (2007). As discussed in the Introduction, they determined flatfields by minimizing errors in relative photometry of multiply observed stars over the whole survey region. Hence, this comparison is an essentially independent test of flatfield corrections derived here despite the fact that both catalogs are based on the same observations. We bin the photometric differences between the catalogs in 0.01° wide Dec bins and compute the median residual for each bin and band. The median value of these medians represent zeropoint offsets in each band and are equal to -7, 2, -1, 2 and 5 millimag in the *ugriz* bands, respectively. The rms scatter of the median residuals reflects systematic errors due to flatfield errors and we measure 27, 6, 5, 6, and 8 millimag in the *ugriz* bands, respectively. Except in the *u* band, these values indicate that systematic flatfield errors are very small. In the *u* band, Padmanabhan et al. (2007) expect errors of about 0.01 mag, and the distribution width of the *s* color implies about 0.01 mag for the catalog discussed here, predicting about 14 millimag instead of the measured 27 millimag. It is plausible that the *u* band photometry may contain systematic errors unrecognized by any of the methods discussed here.

2.7.2. *The tests of catalog quality based on galaxy colors*

The color distribution of galaxies is bimodal (Strateva et al. 2001, Yasuda et al. 2001, Baldry et al. 2003). Red galaxies have an especially tight color-redshift relation (Eisenstein et al. 2001), with an rms of 0.12 mag for the $u - g$ color, 0.05 mag for $g - r$, and 0.03 mag for the $r - i$ and $i - z$ colors (using model magnitudes). Deviations from the mean relations can thus be used to track local calibration problems. Of course, since this is a color-based method, it can only constrain δ_{mr} , and, because red galaxies are faint in the *u* band, cannot achieve high spatial resolution in this band. Nevertheless, it is a useful addition to the stellar locus method because it is independent of the Milky Way structure and secondary star network (although it is sensitive to errors in the ISM dust extinction correction).

We select 19,377 red galaxies with SDSS spectra from the redshift range 0.02–0.36 using an empirical condition

$$0 < (g - r) - 0.6 - 2.75 \times \text{redshift} < 0.3, \quad (9)$$

and determine their median colors as a function of redshift using 0.01 wide redshift bins. The residuals from the median color-redshift relation are then binned by declination to constrain δ_m^{ff} and by right ascension to constrain δ_m^{ext} . The rms for color residuals and the widths of distributions of residuals normalized by statistical noise (based on quoted photometric errors) are listed in Table 6.

The residuals binned in the declination direction are generally small and consistent with statistical noise. The largest deviations from 0 are seen for the $i - z$ color, with an rms of 9 millimag and maximum deviation of 17 millimag (see top panel in Figure 12). Although the rms is fairly small, it is a factor of 2.9 larger than the expected noise. The shape of the $i - z$ residuals is similar to the $i - z$ residuals for stars discussed in § 2.5.2 and shown in the bottom panel in Figure 7. The rms scatter for the difference between the stellar and galaxy $i - z$ residuals, shown in the bottom panel in Figure 12, is 6 millimag. Since the rms for galaxy residuals is larger (9 millimag), it is plausible that the same systematic effect dominates the remaining photometric errors for both stars and galaxies. While it is not clear what the cause of this (small) effect is, a plausible explanation is the dependence of flatfields on source color¹⁹.

The results for binning in the right ascension direction are shown in Figure 13, where we compare different methods. The rms for implied color errors (with 2° wide bins) from galaxies is 0.006 mag for the $r - i$ and $i - z$ colors, 0.012 mag for the $g - r$ color, and 0.018 mag for the $u - g$ color. The overall behavior of red galaxy color residuals agrees better with the PT method, than with color errors implied by the stellar locus method. In particular, the large errors outside the $-25^\circ < \text{RA} < 40^\circ$ range implied by the latter method are not consistent with red galaxy color residuals. On the other hand, both red galaxy colors and stellar locus seem to show a trend that the colors are *redder* around $\text{RA} = -10^\circ$ than around $\text{RA} = 40^\circ$. The amplitude of this effect varies from about 0.02 mag for the $g - r$ color to about 0.01 mag for the $i - z$ color, while the upper limit on such a slope implied by the PT comparison is < 0.01 mag.

It is not clear what the cause of this discrepancy is. The obvious culprit is the correction for interstellar dust extinction, but the implied deviation is too large to be explained by any plausible errors in the SFD98 maps. As shown in Figure 11, the median extinction in the r band for the $-10 < \text{RA} < 40$ range is below 0.1 mag, and the resulting median correction for, e.g., the $g - r$ color is below 0.04 mag. Hence, to induce a 0.02 mag trend in the $g - r$ color, the SFD value for the r band extinction, A_r , would have to be in error by 0.05 mag (the difference between the values provided for $\text{RA} = -10^\circ$ and $\text{RA} = 40^\circ$). This implies relative errors for the SFD map in the range from 50% (if A_r at $\text{RA} = -10^\circ$ is underestimated) to 100% (if A_r at $\text{RA} = 40^\circ$ is overestimated), which seems unlikely (although not impossible).

We conclude that the PT comparison provides a good estimate of the remaining ze-

¹⁹It is fair to ask whether the applied flatfield corrections, derived from stellar colors, are actually appropriate for galaxies. They are since the $i - z$ color residuals for galaxies without any flatfield corrections are about twice as large than those shown in the top panel in Figure 12.

point errors in the catalog, as listed in Table 5, but caution that we do not understand the above systematic behavior of stellar and galaxy colors, and that only the PT constrains possible gray errors. In the next Section, we discuss a comparison to an external dataset, that supports this conclusion.

2.7.3. An external test of catalog quality based on Stetson’s standards

The only large external dataset with sufficient overlap, depth and accuracy to test the quality of the Stripe 82 catalog is that provided by Stetson (2000, 2005). Stetson’s catalog lists photometry in the *BVRI* bands (Stetson’s photometry is tied to Landolt’s standards) for $\sim 1,200$ stars in common (most have $V < 19.5$). We synthesize the *BVRI* photometry from SDSS *gri* measurements using photometric transformations of the following form

$$m_{\text{Stetson}} - m_{\text{SDSS}} = A c^3 + B c^2 + C c + D, \quad (10)$$

where $m_{\text{Stetson}} = (BVRI)$ and $m_{\text{SDSS}} = (g, g, r, i)$, respectively, and the color c is measured by SDSS ($g-r$ for the *B* and *V* transformations, and $r-i$ for the *R* and *I* transformations). The measurements are *not* corrected for the ISM reddening. Traditionally, such transformations are assumed to be linear in color²⁰. We use higher-order terms in eq. 10 because at the 1-2% level there are easily detectable deviations from linearity for all color choices (for details and plots see Ivezić et al. 2007). The best-fit coefficients for the transformation of SDSS *gri* measurements to the *BVRI* system²¹, and low-order statistics for the $m_{\text{Stetson}} - m_{\text{SDSS}}$ difference distribution²² are listed in Table 7. We find no trends as a function of magnitude at the < 0.005 mag level. With the listed transformations, *the SDSS catalog described here could also be used to calibrate the data to the BVRI system with a negligible loss of accuracy due to transformations between the two systems.*

The *BVRI* photometry from Stetson and that synthesized from SDSS agree at the level of 0.02 mag (rms scatter for the magnitude differences of *individual* stars; note that the systems are tied to each other to within a few millimags by the transformations listed in Table 7). This scatter is consistent with the claimed accuracy of both catalogs (the magnitude

²⁰For various photometric transformations between the SDSS and other systems, see Abazajian et al. (2005) and <http://www.sdss.org/dr5/algorithms/sdssUBVRITransform.html>.

²¹ The same transformations can be readily used to transform measurements in the *BVRI* system to the corresponding *gri* values because $B - V = f(g - r)$ and $R - I = f(r - i)$ are monotonic functions.

²²Note that these transformations are valid *only* for main sequence stars with colors in the range $g - r > 0.2$ and $r - i < 1.5$ (roughly, $0.3 < B - V < 1.6$). Extrapolation outside this range may result in large errors!

differences normalized by the implied error bars are well described by Gaussians with widths in the range 0.7–0.8). This small scatter allows us to test for the spatial variation of zeropoints between the two datasets, despite the relatively small number of stars in common.

Stars in common are found in four isolated regions that coincide with historical and well-known Kapteyn Selected Areas 113, 92, 95, and 113. We determine the zeropoint offsets between the SDSS and Stetson’s photometry for each region separately by synthesizing *BVRI* magnitudes from SDSS *gri* photometry, and comparing them to Stetson’s measurements. The implied zeropoint errors (which, of course, can be due to either the SDSS or the Stetson dataset, or both) are listed in Table 8. For regions 1-3 the implied errors are only a few millimags (except for the $B - g$ color in region 1). The discrepancies are much larger for the three red colors in region 4. A comparison with the results of internal SDSS tests described in §2.7.1 and 2.7.2 suggests that these discrepancies are more likely due to zeropoint offsets in Stetson’s photometry for this particular region, than to problems with SDSS photometry. We contacted P. Stetson who confirmed that his observing logs were consistent with this conclusion. Only a small fraction of stars from Stetson’s list are found in this region.

Given the results presented in this Section, we conclude²³ that the rms for the spatial variation of zeropoints in the SDSS Stripe 82 catalog is below 0.01 mag in the *gri* bands.

3. The Utility of the SDSS Stripe 82 Standard Star Catalog

As examples of the use of the standard star catalog, we discuss calibration of data obtained in non-photometric conditions, and a detailed and robust measurement of the morphology of the stellar locus in color-color space.

3.1. Calibration of Non-photometric Data

The existence of a technique to photometrically calibrate non-photometric data would greatly increase the efficiency of telescopes. As one particular example of how our catalog can support a large project, consider the SDSS-II Supernova survey (Sako et al. 2005). This survey aims to obtain repeat images of stripe 82 with a sufficient cadence to enable discovery of new type Ia supernovae. This requirement sometimes results in observations obtained

²³Here we assumed that it is a priori unlikely that the SDSS and Stetson’s zeropoint errors are spatially correlated.

through clouds with several magnitudes of extinction. In such highly non-photometric conditions the standard photometric calibration described in section 2.2 fails because the fields with standard stars are too sparsely distributed to be able to resolve fast variations in cloud extinction.

3.1.1. A method to track fast cloud extinction variations

Due to its high stellar density, the standard star catalog described in this paper can be used for calibration of data obtained in grossly non-photometric conditions. The typical number of calibration stars in each SDSS field (9×13 arcmin²) at high Galactic latitudes is 10-15 in the *u* band, 40-50 in the *gri* bands, and 30-40 in the *z* band. Based on tests of several non-photometric SDSS-II runs, it was found that the cloud extinction variations can be tracked with a sufficient temporal resolution (~ 3 sec) to obtain photometric zeropoint accuracy comparable to that characteristic for photometric nights (1-2% in *gri* and 2-3% in *u* and *z*; Ivezić et al. 2004a).

The calibration is done in two steps. First, the implied zeropoints (whose variation is dominated by cloud extinction), *zp*, defined by

$$m_{calibrated} = -2.5 * \log(counts) + zp, \quad (11)$$

are computed for each star and median filtered in time using a window with 5 stars in order to avoid outliers. Note that we assume that clouds are gray and do not allow for color terms, an assumption which is justified a posteriori (see §3.1.4). In the second step, zeropoints are evaluated for each 2048 pixel wide (cross-scan direction) and 100 pixel long (in-scan direction) image segment, hereafter called a calibration patch (not to be confused with secondary star patches discussed in §2.2). That is, a calibration patch is a ~ 9 arcmin² large rectangle with an aspect ratio 1:20, and the zeropoints are evaluated every 2.6 seconds of time (but note that the variations are smoothed out by the 54 sec long exposure time).

The patch is much narrower in the in-scan direction because tests have shown that zeropoint gradients across a field are much larger, by a factor 10-50, in this direction (see Figure 14). Consider three stars, star A, a star B that is, say, 25 arcmin (the column-to-column separation) away from the star A in the scan direction, and a star C that is 25 arcmin away from the star A in the cross-scan direction. Stars A and C are observed at the same time and the difference in their implied zeropoints measures the structure function of cloud opacity on a 25 arcmin spatial scale. This is true irrespective of the cloud motion relative to the boresight. Here, the structure function of cloud opacity (SF hereafter) is defined as the rms width of the distribution of zeropoint differences evaluated for pairs of points separated

by some distance.

On the other hand, stars A and B are observed at times that differ by 1.7 minutes. If the component of the cloud angular velocity on the sky relative to the boresight and parallel to the scanning direction is ω $^{\circ}$ min^{-1} , the zeropoint difference for stars A and B samples the cloud structure on spatial scales of $25 \omega/\omega_s$ arcmin, where $\omega_s=0.25$ $^{\circ}$ min^{-1} is the sidereal scanning rate (here for simplicity we assumed $\omega \gg \omega_s$, which is supported by the data). The observed behavior of zeropoints, such as that shown in Figure 14, implies wind velocity in the range²⁴ $\omega=3-15$ $^{\circ}$ min^{-1} , or $\omega/\omega_s \sim 12-60$. Hence, drift scanning has the unfortunate property that the motion of an inhomogeneous extinction screen with a speed much larger than the sidereal scanning rate greatly magnifies the effective zeropoint variations in the scan direction.

The zeropoints for each calibration patch are computed by taking all the stars from the patch, or finding the closest three stars for sparsely populated patches, and adopting the median value of their zeropoints. This is certainly not the only, nor perhaps the ideal approach to calibrate patches, but we found that it works well in practice. The zeropoint error is evaluated from the root-mean-square scatter of zp evaluated for each calibration star, divided by the square root of the number of stars. We now discuss the performance of this method.

3.1.2. Performance and Quality Tests

The top panel in Figure 15 summarizes the behavior of cloud extinction in the r band, as measured by the zeropoint zp discussed above, for an SDSS-II SN run (5646) obtained in strongly non-photometric conditions. Although the cloud extinction during the first 90 minutes (corresponding to 150 SDSS fields) varies between 0 and ~ 6 mag, it is possible to robustly calibrate these data. Figure 16 zooms in on a 8 minute stretch of the same data where the cloud extinction varies between 0 and ~ 3 mag, with changes as fast as 0.05 mag s^{-1} (almost 2 mag per SDSS field!). As shown in the figure (middle left panel), the residuals have a distribution width of only 0.07 mag. The middle right panels in Figures 15 and 16 demonstrate that most of this scatter is contributed by random photometric errors (i.e. errors in extracted source counts), rather than by calibration errors (large cloud extinction results in a smaller number of calibration stars, as well as in a lower SNR for those calibration

²⁴This range is equivalent to angular speeds of up to a half of the Moon’s diameter per second. The plausibility of this wind velocity range was verified in extensive visual observations of the full Moon during frequent grossly non-photometric nights in Seattle.

stars that are detected). Even with such a large and rapidly varying cloud extinction, the zeropoint errors are smaller than 0.05 mag, with a median value of less than 0.02 mag. An example of a run with somewhat thinner and much more stable cloud cover is shown in Figure 17.

The calibration performance in other bands is similar. For example, although the number of calibration stars is smaller in the u band than in the r band, the median zeropoint error for the same stretch of data as shown in Figure 17 is still only 0.01 mag, as illustrated in Figure 18.

3.1.3. *The Summary of Calibration Accuracy*

A summary of the final zeropoint errors as a function of cloud extinction and band for one of the worst runs is shown in the left column in Figure 19. As the figure shows, the data can be calibrated with small zeropoint errors even for such a bad case. Typically, the zeropoint errors, for the same cloud extinction, are about twice as small as in this run. A calibration summary for a run with optically thick, but exceptionally smooth, clouds is shown in the right column in Figure 19. Overall, *for cloud extinction of X mag, the zeropoint uncertainty is typically smaller than $(0.02 - 0.05)X$ for 95% of calibration patches, with a median of $(0.01-0.02)X$.*

3.1.4. *The Cloud Color and Structure Function*

We detect no dependence of the calibration residuals on the stellar color or cloud thickness at a few millimag level. This is consistent with the lack of selective extinction by clouds. The lack of a color correlation in the u and z bands implies that the well-known cloud grey-ness extends beyond visual wavelengths. Another method to quantify selective extinction by clouds is to directly compare zeropoints from different bands. As shown in Figure 20, the cloud extinction is similar in all bands for most fields. A few cases where there are deviations of a few tenths of a magnitude can be easily understood as due to temporal changes in the cloud opacity (recall that the data from different bands are obtained over ~ 5 minutes of time).

The calibration accuracy is determined by the size of the calibration patches. For example, a smaller patch would suffer less from the spatial variation of cloud extinction, but it wouldn't have enough stars to beat down the noise of their individual photometric measurements (~ 0.02 mag for sufficiently bright stars). The detailed scaling of this accuracy

with patch size depends on the cloud spatial structure function. The geometry of the SDSS camera allows us to study the cloud SF on scales exceeding 2° . Figure 21 compares zeropoints in different columns for two runs with significantly different cloud behavior. While zeropoints from different columns generally track each other, there can be differences exceeding a magnitude (they generally scale with the cloud optical thickness). These differences increase with the distance between the camera columns. Figure 22 shows a typical behavior: for small spatial scales ($<2^\circ$) the SF is roughly a linear function of distance, and it scales roughly linearly with the cloud extinction. *At a 1° scale, the SF is typically of order 2-10% of the cloud extinction.* For example, even for clouds 3 mag thick, the SF at 2 arcmin scales is typically <0.01 mag.

3.1.5. Implications for Surveys such as LSST

The Large Synoptic Survey Telescope (LSST) is a proposed imaging survey that will attempt to maximize its observing time by accepting non-photometric conditions. At the same time, it has adopted exquisite requirements for its photometric accuracy, including 1% accuracy of its internal photometric zeropoint errors across the sky. Our analysis allows us to answer the following question: “What is the largest cloud extinction that still allows photometric calibration accurate to 1%?”.

A similar approach to the calibration of LSST data as presented here (assuming that a standard star catalog is available, e.g. from prior demonstrably photometric nights) would benefit from several effects:

1. The LSST will not use a drift-scanning technique and thus the calibration patches can be squares; for the same area, this results in a ~ 5 times smaller angular scale (~ 3 arcmin), compared to the 1:20 rectangles we have used to calibrate SDSS drift-scanning data. On these angular scales, the cloud structure function is roughly linear and thus the zeropoint error would be ~ 5 times smaller, or of the order 1% or less through clouds as thick as 1 mag (conservatively assuming that SDSS errors would be $0.05X$, see § 3.1.3). We note that the shorter exposure time for LSST (30 seconds, or about a factor of two shorter than for SDSS) is not relevant because clouds would typically move by more than a degree during the exposure. This is more than an order of magnitude larger distance than the size of the calibration patch and thus the structure function analysis remains valid.
2. LSST data will be deeper than SDSS by about 2-3 mag. With a conservative assumption that $\log N \propto 0.3m$ for faint stars (0.6 for Euclidean counts), the surface density

of calibration stars will be about ten times larger for LSST than for SDSS. This larger density enables ten times smaller patches, or about three times smaller angular scale for calibration (~ 1 arcmin), resulting in another factor of three improvement of accuracy.

3. Fitting a smooth function for cloud opacity over several calibration patches would result in further improvements.

The first two points predict that *LSST data could be calibrated with the required 1% accuracy even through 3 mag thick clouds*. Given the various extrapolations, we conservatively suggest the range of 1-3 mag as the upper limit on the acceptable cloud opacity²⁵.

3.2. The Morphology of the Stellar Locus

The improved accuracy of averaged photometry provides "crisper" color-color diagrams and also reveals new morphological features. An example of such a color-color diagram is shown in Figure 23.

This is a similar plot to Figure 1 from Smolčić et al. (2004), except that *only* non-variable point sources are shown (note the absence of quasars) and averaged photometry is used. The white dwarf/M dwarf "bridge" discussed by Smolčić et al. is clearly visible, as well as the locus of probable solar metallicity giants (this identification is based on models, e.g. Kurucz 1979) which bifurcates from the main locus at $u - g \sim 2.5$ and $g - r \sim 1$. Note also the well-defined BHB locus ($u - g \sim 1.1$ and $g - r$ from -0.3 to 0.1) and the white dwarf locus ($u - g \sim 0.35$ and $g - r$ from -0.3 to ~ 0.0). A new locus-like feature, that is *not* visible in Figure 1 from Smolčić et al., is discernible at $u - g \sim 0$ and $g - r \sim -0.2$. The great value of the accurate u band photometry is clearly evident at e.g. $g - r = -0.2$: the $u - g$ color distribution is tri-modal! The bluest branch is consistent with He white dwarfs, and the middle branch with hydrogen white dwarfs, as supported by Bergeron et al. (1995) white dwarf models and detailed analysis of SDSS spectra (Eisenstein et al. 2006). The reddest branch is made of blue horizontal branch stars (see Sirko et al. 2004 and references therein).

The exciting fact that *one can distinguish He and H white dwarfs using photometry alone* is a consequence of the improved photometric accuracy due to averaging many epochs. Figure 24 reiterates that point. Note the striking difference between the two bottom panels:

²⁵Of course, cloud opacity decreases the imaging depth and data with clouds thicker than ~ 1 mag may be undesirable for reasons other than calibration accuracy.

while one could be convinced that the He white dwarf sequence is a real feature in the bottom right panel, its existence is clearly evident when using the improved photometry, as shown in the bottom left panel. In summary, *the multi-epoch observations provide both the identification of variable sources and much more accurate colors for non-variable sources.* This bodes well for science deliverables from upcoming large-scale imaging surveys. For example, LSST will obtain over its 10-year long mission similar repeat imaging as discussed here, but about 2.5 mag deeper, with about 100 or more observations per band and object, and over about two orders of magnitude larger area. Although these new surveys will not have a spectroscopic component like SDSS did, the multi-epoch nature of their imaging will provide alternative information-rich datasets.

4. Discussion and Conclusions

Using repeated SDSS measurements, we have constructed a catalog of over a million candidate standard stars. The catalog is publicly available from the SDSS website²⁶. Several independent tests suggest that both internal zeropoint errors and random photometric errors for stars brighter than (19.5, 20.5, 20.5, 20, 18.5) in *ugriz*, respectively, are at or below 0.01 mag (about 2-3 times better than for an individual SDSS scan). This is by far the largest existing catalog with multi-band optical photometry accurate to $\sim 1\%$, and breaks the accuracy barrier discussed by e.g. Stubbs & Tonry (2006, and references therein). These observations were not obtained for the specific purpose of calibration, but were part of the regular SDSS observational program. When compared to, for example, the heroic calibration efforts by Landolt, Stetson, and others, it seems justified to call the method presented here "industrial" photometry. However, the catalog presented here is not without its problems.

The selection of candidate stars was simply based on the absence of variability. It is fairly certain that not all variable sources are recognized because of the limited number of repeated observations (~ 10). For example, an eclipsing binary with much shorter eclipse duration than the orbital period could easily escape detection. Furthermore, some of these sources may not even be stars. A cross-correlation with the SDSS spectroscopic database yields 99,000 matches in the overlapping region, including 44,000 spectra classified as stars. About 70 candidate standard stars are actually spectroscopically confirmed quasars! Apparently, a small fraction of quasars (a few percent, for a detailed analysis see Sesar et al. 2007, in prep.) cannot be detected by variability (at least not using the number of epochs, their time distribution, and photometric accuracy employed in this work). Indeed, we have also

²⁶See http://www.sdss.org/dr5/products/value_added/index.html

found three spectroscopically confirmed SDSS quasars among Stetson’s standards which were observed 20-30 times and which showed no variation. Similarly, about 300 candidate standard stars have SDSS spectra classified as galaxies. Nevertheless, the inspection of color-color diagrams strongly suggest that the overwhelming majority of the standard stars are found on the stellar locus.

Remaining systematic errors are another important concern. Effectively, we have assumed that PT problems average out in many patches when deriving flatfield corrections using stellar colors. This may not be true at a level not much smaller than 1%, and thus the remaining gray problems at such a level may be present in the catalog. Despite these residual problems, we believe that internal consistency of the catalog (i.e. when ignoring Δ_m from eq. 4) is such that the rms width for the function $\delta_m(\text{RA}, \text{Dec})$ from eq. 4 evaluated for all stars in the catalog is at most 0.01 mag in the *griz* bands and perhaps just slightly larger in the *u* band (very unlikely exceeding 0.02 mag). In addition to gray problems and overall flatfield errors, the dependence of flatfields on source color is probably the largest remaining systematic error.

We illustrate several use cases for this catalog, including the calibration of highly non-photometric data and robust selection of stars with peculiar colors. We find that LSST and similar surveys will be able to observe in partially cloudy (non-photometric) nights because even cloudy data can be accurately calibrated with a sufficiently dense network of calibration stars. Such a dense network will be self-calibrated by LSST very soon after first light, using an approach developed for SDSS data by Padmanabhan et al. (2007). Given such a network, SDSS experience suggests that LSST can maintain its required photometric calibration accuracy of 1% even when observing through 1-3 mag thick clouds.

Perhaps the most exciting conclusion of this work is that it may become obsolete in only a few years due to the advent of next-generation surveys such as Pan-STARRS and LSST.

Acknowledgments

We are thankful to Peter Stetson for his most useful comments and for providing his latest standard star photometry to us. Ž. Ivezić and B. Sesar acknowledge support by NSF grant AST-0551161 to LSST for design and development activity, and H. Morrison acknowledges support by NSF grant AST-0607518.

^cThe minimum value for the median residuals (in millimag).

^dThe maximum value for the median residuals (in millimag).

^eThe median number of stars per bin.

^fThe median value of the residuals for stars with colors within 0.02 mag from the crossing colors (in millimag).

Table 6. Residuals from the mean color-redshift relation^a for red galaxies.

color	rms(Dec) ^b	χ (Dec)	rms(RA) ^c	χ (RA)
$u - g$	21	1.5	18	1.3
$g - r$	4	1.3	12	2.6
$r - i$	3	1.3	6	3.5
$i - z$	9	2.9	6	2.9

^aThe table lists the rms widths of color-residual distributions (in millimag), and the widths of distributions of residuals normalized by statistical noise (χ), using mean color-redshift relations (see text).

^bThe rms for the declination direction, using 0.025° wide bins (0.1° for the $u - g$ color).

^cThe rms for the right ascension direction, using 2° wide bins (5° for the $u - g$ color).

Table 7. Comparison with Stetson’s standards: I. *griz* to *BVRI* transformations^a

color	$\langle \rangle_{med}^b$	σ_{med}^c	χ_{med}^d	$\langle \rangle_{all}^e$	σ_{all}^f	A^g	B^g	C^g	D^g
$B - g$	-1.6	8.7	1.4	1.0	32	0.2628	-0.7952	1.0544	0.0268
$V - g$	0.8	3.9	1.0	0.9	18	0.0688	-0.2056	-0.3838	-0.0534
$R - r$	-0.1	5.8	0.9	1.2	15	-0.0107	0.0050	-0.2689	-0.1540
$I - i$	0.9	6.1	1.0	1.2	19	-0.0307	0.1163	-0.3341	-0.3584

^aThese transformations are valid *only* for main sequence stars with colors in the range $g - r > 0.2$ and $r - i < 1.5$ (roughly, $0.3 < B - V < 1.6$). Extrapolation outside this range may result in large (0.1 mag or larger for hot white dwarfs) errors!

^bThe median value of median transformation residuals (differences between the measured values of colors listed in the first column and those synthesized using eq. 10) in 0.1 mag wide $g - r$ bins for stars with $0.25 < g - r < 1.45$ (in millimag). These medians of medians measure the typical level of systematics in the *gri*-to-*BVRI* photometric transformations introduced by the adopted analytic form (see eq. 10).

^cThe root-mean-square scatter for median residuals described above (in millimag).

^dThe root-mean-square scatter for residuals normalized by statistical noise. The listed values are ~ 1 , which indicates that the scatter around adopted photometric transformations listed under b) is consistent with expected noise.

^eThe median value of residuals evaluated for all stars (in millimag).

^fThe root-mean-square scatter for residuals evaluated for all stars (in millimag).

^gCoefficients A–D needed to transform SDSS photometry to the *BVRI* system (see eq. 10).

Table 8. Comparison with Stetson’s standards: II. Photometric zeropoint variations

color	$\langle \rangle_{R1}^a$	σ_{R1}^b	N_{R1}^c	$\langle \rangle_{R2}^a$	σ_{R2}^b	N_{R2}^c	$\langle \rangle_{R3}^a$	σ_{R3}^b	N_{R3}^c	$\langle \rangle_{R4}^a$	σ_{R4}^b	N_{R4}^c
$B - g$	−29	21	92	6	27	165	8	42	155	−4	27	281
$V - g$	0	17	99	0	15	217	6	25	161	17	19	282
$R - r$	−6	16	58	4	16	135	−8	12	11	39	27	60
$I - i$	−11	16	94	6	18	205	2	16	124	19	15	47

^aThe median value of residuals (in millimagnitudes) for transformations listed in the first column, evaluated separately for regions 1-4, defined as: **R1**: RA~325, Dec<0; **R2**: RA~15; **R3**: RA~55; **R4**: RA~325, Dec>0.

^bThe root-mean-square scatter for the transformation residuals (in millimagnitudes).

^cThe number of stars in each region with good photometry in the required bands.

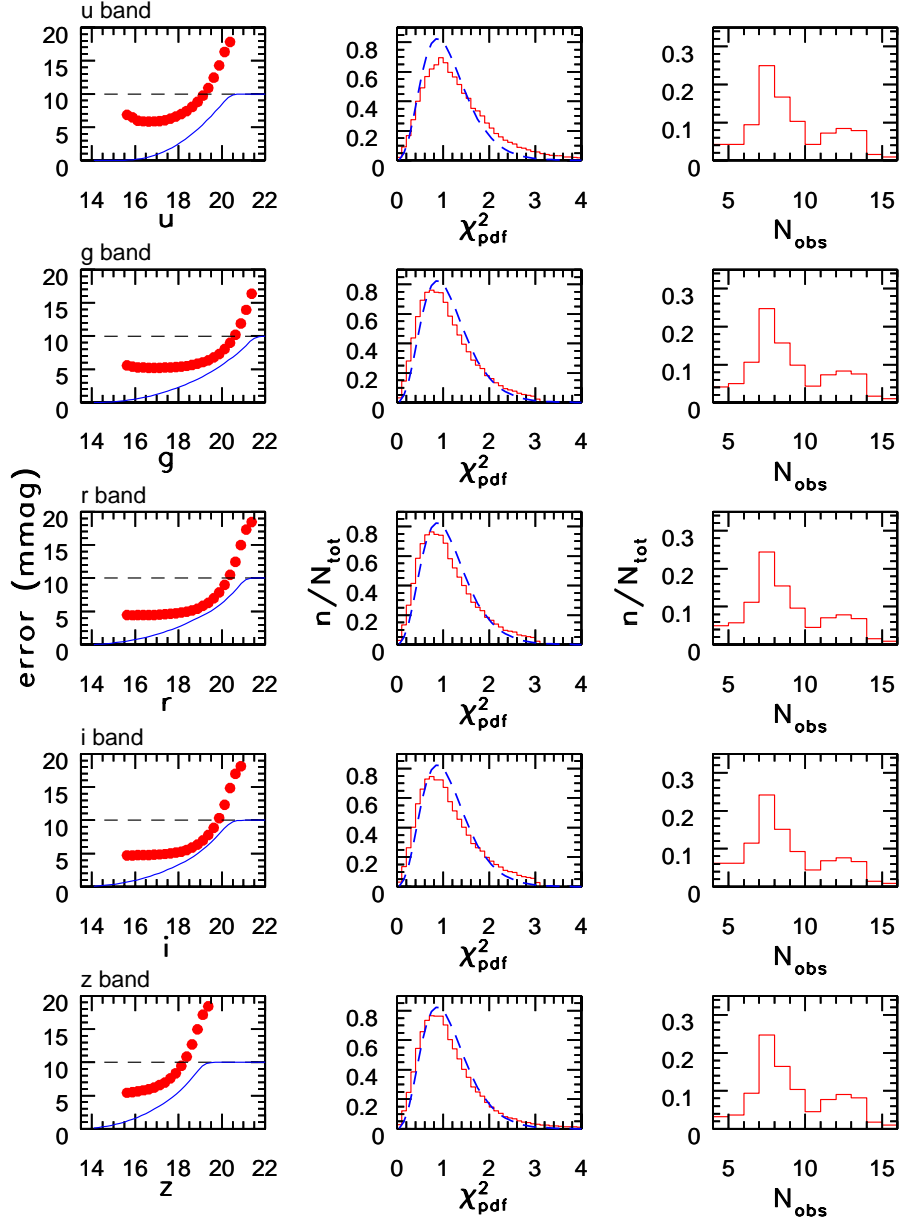

Fig. 1.— The median magnitude error as a function of magnitude (left column, symbols), the χ^2 per degree of freedom distribution (solid line, middle column), and the number of observations in each band (right column) for candidate standard stars from SDSS stripe 82 (selected by $\chi^2 < 3$ in the *gri* bands). The solid lines in the left column show cumulative magnitude distribution normalized to 10 at the faint end. The dashed lines in the middle column show the χ^2 per degree of freedom distribution for a Gaussian error distribution and nine degrees of freedom. Its similarity with the measured distributions suggests that the magnitude errors computed by the photometric pipeline are reliable (they may be slightly underestimated, by about 10%, in the *u* band).

Fig. 2.— A comparison of the color-magnitude and color-color distributions for variable and non-variable unresolved sources from SDSS stripe 82. The distributions of sources with a root-mean-square (rms) scatter of the g band magnitude below 0.05 mag are shown by linearly-spaced contours (non-variable sources). Sources with $320^\circ < \text{RA} < 330^\circ$, with rms scatter in the g band larger than 0.05 mag, and χ^2 greater than three, are shown by dots (variable sources). The dots are color-coded according to the observed rms scatter in the g band (0.05–0.10 mag, see the legend, red indicates variability larger than 0.1 mag). Note how low-redshift quasars ($u - g < 0.6$) and RR Lyrae ($u - g \sim 1.1$, $g - r \sim 0$; Ivezić et al. 2005) clearly stand out as variable sources (red points).

Fig. 3.— The color-magnitude and color-color distributions of candidate standard stars brighter than $g = 20$. The dots are color-coded according to the observed rms scatter in the g band (0–0.05 mag, see the legend). Note the absence of quasars and RR Lyrae visible in Figure 2.

Fig. 4.— Analogous to Figure 3, except that only variable sources are shown, and with a different color coding (0.05–0.10 mag range of the g band rms, instead of 0–0.05 mag).

Fig. 5.— The top panel shows the sky density of all the point sources with at least 4 observations in each of the g , r and i bands (solid), and of selected candidate standard (non-variable) stars (dashed). The bottom panel shows the ratio of the two curves shown in the top panel. For reference, Galactic coordinates, (l, b) , are $(46, -24)$, $(96, -60)$ and $(190, -37)$ for $\alpha_{J2000} = -50^\circ$, 0° and 60° (at $\delta_{J2000} = 0^\circ$).

Fig. 6.— The top panel compares the five transmission curves, ϕ (see eq.3 for definition), that define the SDSS photometric system (dashed lines), to measured transmission curves sorted by camera column and shown by solid lines, as marked in the panel (the area under each curve is unity by definition). The bottom panel shows the differences between the measured transmission curves and the curves that define the system. These differences induce color terms that result in systematic photometric errors as a function of source color. The largest color terms are present for the z band in camera columns 2 and 6, with the errors well described by $\Delta z_2 = z_2 - z_{\text{SDSS}} = -0.019(r - i)$ and $\Delta z_6 = +0.017(r - i)$ mag, respectively.

Fig. 7.— A test based on the stellar locus position angle in the $i - z$ vs. $r - i$ color-color diagrams that demonstrates the existence of color terms between different camera columns. The y axis shows the difference in the $i - z$ color residuals of blue ($0.1 < r - i < 0.2$) and red ($0.8 < r - i < 1.4$) stars, with the residuals computed as the difference between measured $i - z$ colors and those predicted using the mean stellar locus (see the bottom right panel in Figure 3). The vertical solid lines mark the approximate boundaries between different camera columns, with the vertical dashed lines marking approximate boundaries between the “north” and “south” strips in a stripe (see §2.1 for definitions). The top panel shows results before applying corrections for different transmission curves (see Figure 6) and the bottom panel shows results based on corrected photometry. As evident, the residuals in the bottom panel are much smaller, with rms scatter decreasing from 9 millimag to 3 millimag.

Fig. 8.— The top two panels show two projections of the stellar locus (rotated locus from the ugr and gri planes, see Figure 3) constructed using averaged photometry. The large green dots show the median values of the s and w principal colors (perpendicular to the locus at its blue edge) in bins of the principal color along the locus. The middle and bottom rows show histograms for each principal color on linear and logarithmic scales (essentially the locus cross-sections). The blue (narrow) histograms are constructed using the averaged photometry, and the magenta histograms are based on single-epoch photometry. The former are narrower than the latter due to increased photometric accuracy. The best-fit Gaussians, with parameters listed in the middle row, are shown by the dashed lines in the bottom row (only for the averaged photometry).

Fig. 9.— The top panel shows the distribution of the residuals between the PT photometry and averaged magnitudes in the *gri* bands. The second panel shows applied flatfield correction in the *r* band, which was derived as the mean of the residuals shown in the top panel. The remaining two panels show the applied flatfield corrections in the other four bands, expressed relative to the *r* band (middle: *u*, bottom: *gri*), which were derived using the stellar locus colors. The low-order statistics for these corrections are listed in Table 4.

Fig. 10.— The panels show the dependence of the position of the stellar locus in *ugriz* color space, as parametrized by the median principal colors *swxy*, as a function of RA. Close to the edges, the median colors deviate significantly from 0. This is caused by intrinsic changes in the stellar locus due to stellar population variations and overestimated interstellar extinction corrections for red stars, rather than calibration problems.

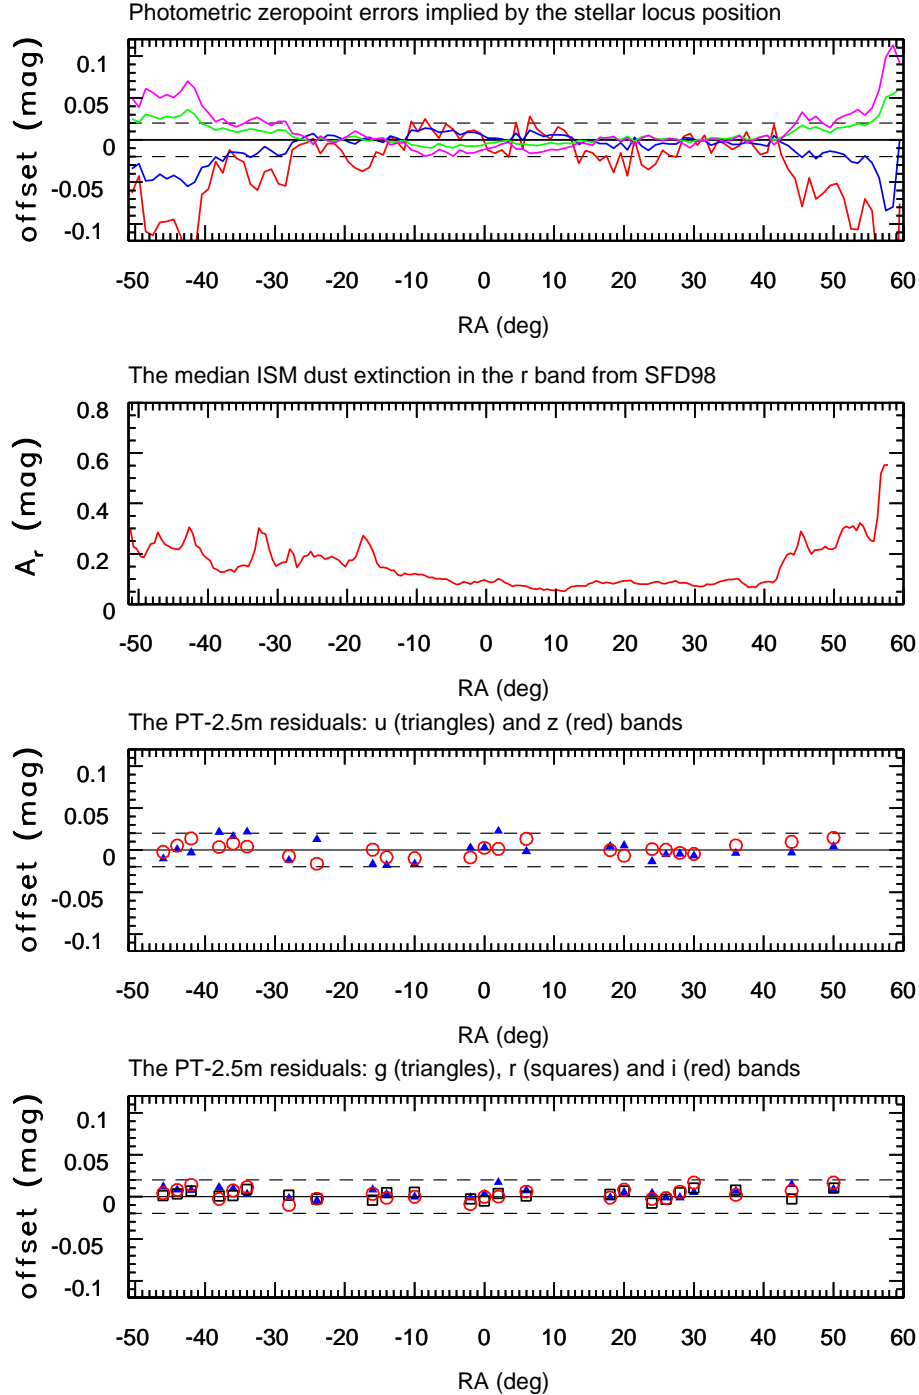

Fig. 11.— The top panel shows the implied photometric zeropoint errors based on the stellar locus method (*ugiz* from the bottom to the top at either edge). While the implied errors are small for $-25 < \text{RA} < 40$, they become exceedingly large outside this range. This is due to problems with the stellar locus method rather than due to problems with calibration. The second panel shows the median *r* band extinction derived from the Schlegel, Finkbeiner & Davis (1998) maps. The bottom two panels show the median residuals between the PT photometry and averaged magnitudes in the *uz* (third row) and *gri* bands (bottom row). The low-order statistics for these residuals are listed in Table 5.

Fig. 12.— The top panel shows the dependence of the median $i - z$ color residuals (with respect to a mean color-redshift relation) for red galaxies as a function of Dec. The vertical solid lines mark the approximate boundaries between different camera columns, with the vertical dashed lines marking approximate boundaries between the “north” and “south” strips in a stripe. The small rms scatter of only 9 millimag demonstrates that flatfield corrections based on the stellar locus position in color space are also applicable for galaxies. The bottom panel shows the difference between the values shown in the top panel and the curve shown in the bottom panel in Figure 7. The rms scatter for the residuals in the bottom panel is 6 millimag.

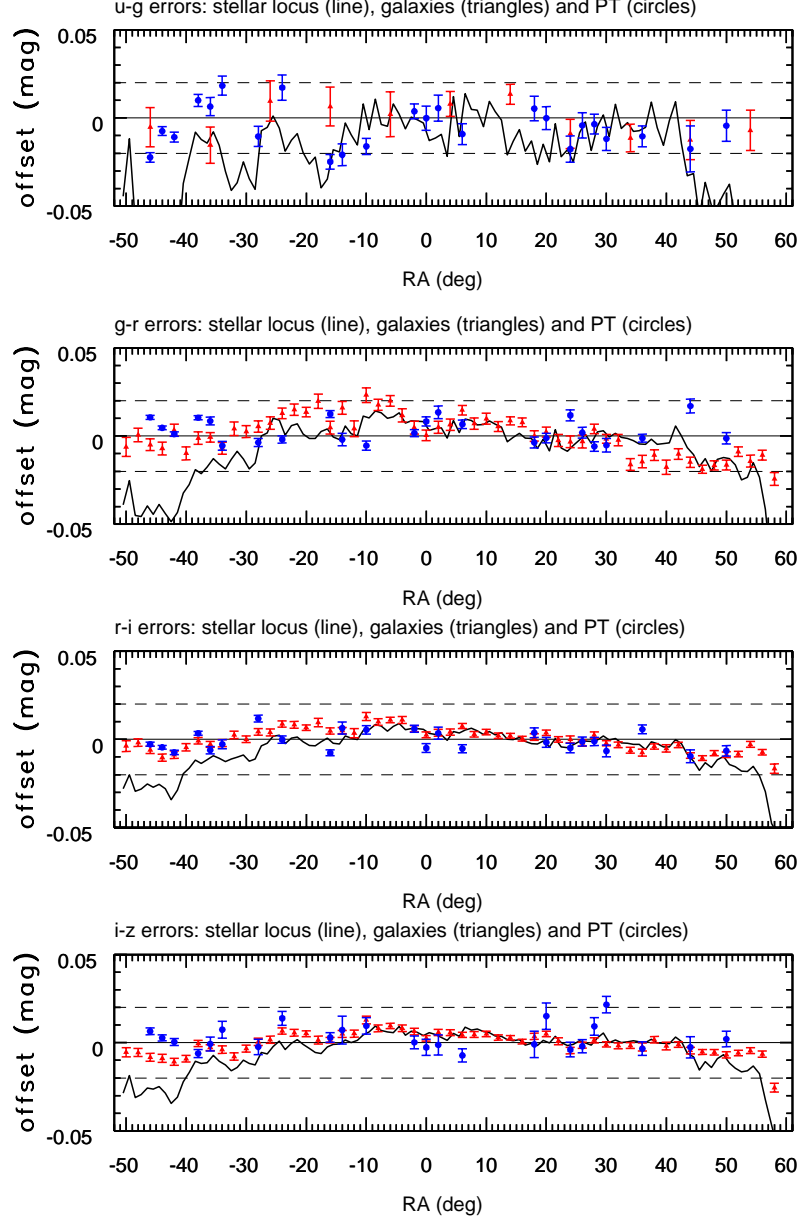

Fig. 13.— The comparison of systematic color errors implied by different methods. Note that the errors implied by the stellar locus method (line) become very large outside the $-25^\circ < \alpha_{J2000} < 40^\circ$ range. As galaxy colors (triangles) and a direct comparison with SDSS secondary standard star network (circles) suggest, this is due to problems with the stellar locus method rather than due to problems with calibration.

Fig. 14.— The comparison of cloud extinction gradients in the in-scan (RA, horizontal axis) and cross-scan (Dec, vertical axis) directions for SDSS run 5759, on a spatial scale of $\sim 0.4^\circ$ (each point is derived using zeropoints from three calibration patches). Note the different axis scales. For this particular run, the distribution width is 9.6 times larger for the in-scan than for the cross-scan direction. This is a consequence of cloud motion relative to the boresight, and the drift-scanning technique.

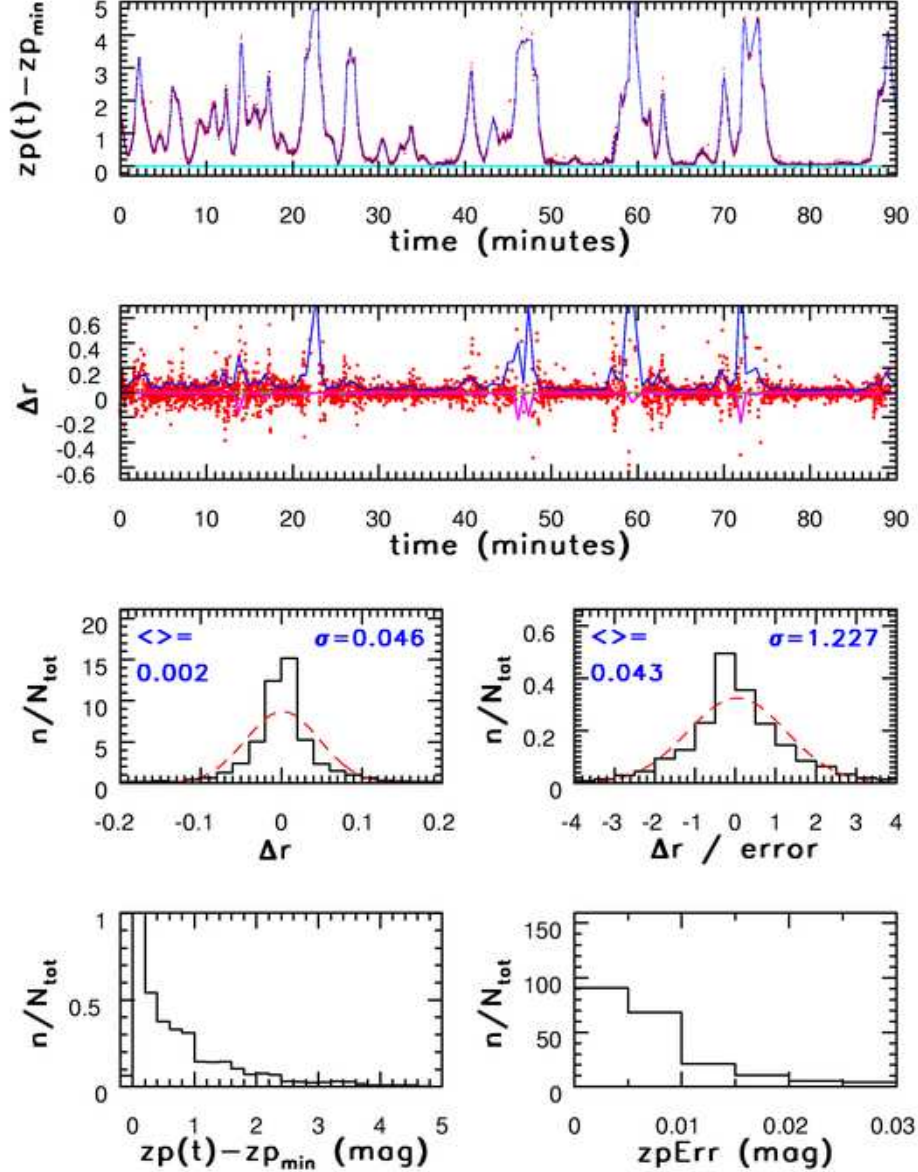

Fig. 15.— The top panel summarizes the behavior of cloud extinction in the r band over 1.5 hours during SDSS-II run 5646. Individual calibration stars are shown by dots, and the adopted zeropoint is shown by the line. The calibration residuals for each star are shown by dots in the second panel. The root-mean-square scatter for these residuals evaluated for each field is shown by the line. The distribution of the residuals is shown in the left panel in the third row as the solid line. The median and equivalent Gaussian σ evaluated from the inter-quartile range are also shown in the panel, as well as a Gaussian corresponding to these parameters (dashed line). The right panel is analogous, except that the residuals are normalized by the expected errors. The distribution of implied cloud extinction is shown in the bottom left panel, and the distribution of standard errors for the adopted photometric zero-points (computed from the rms width of the distribution of residuals) is shown in the bottom right panel (a few points, about 4 out of 1800 calibration patches, are off scale).

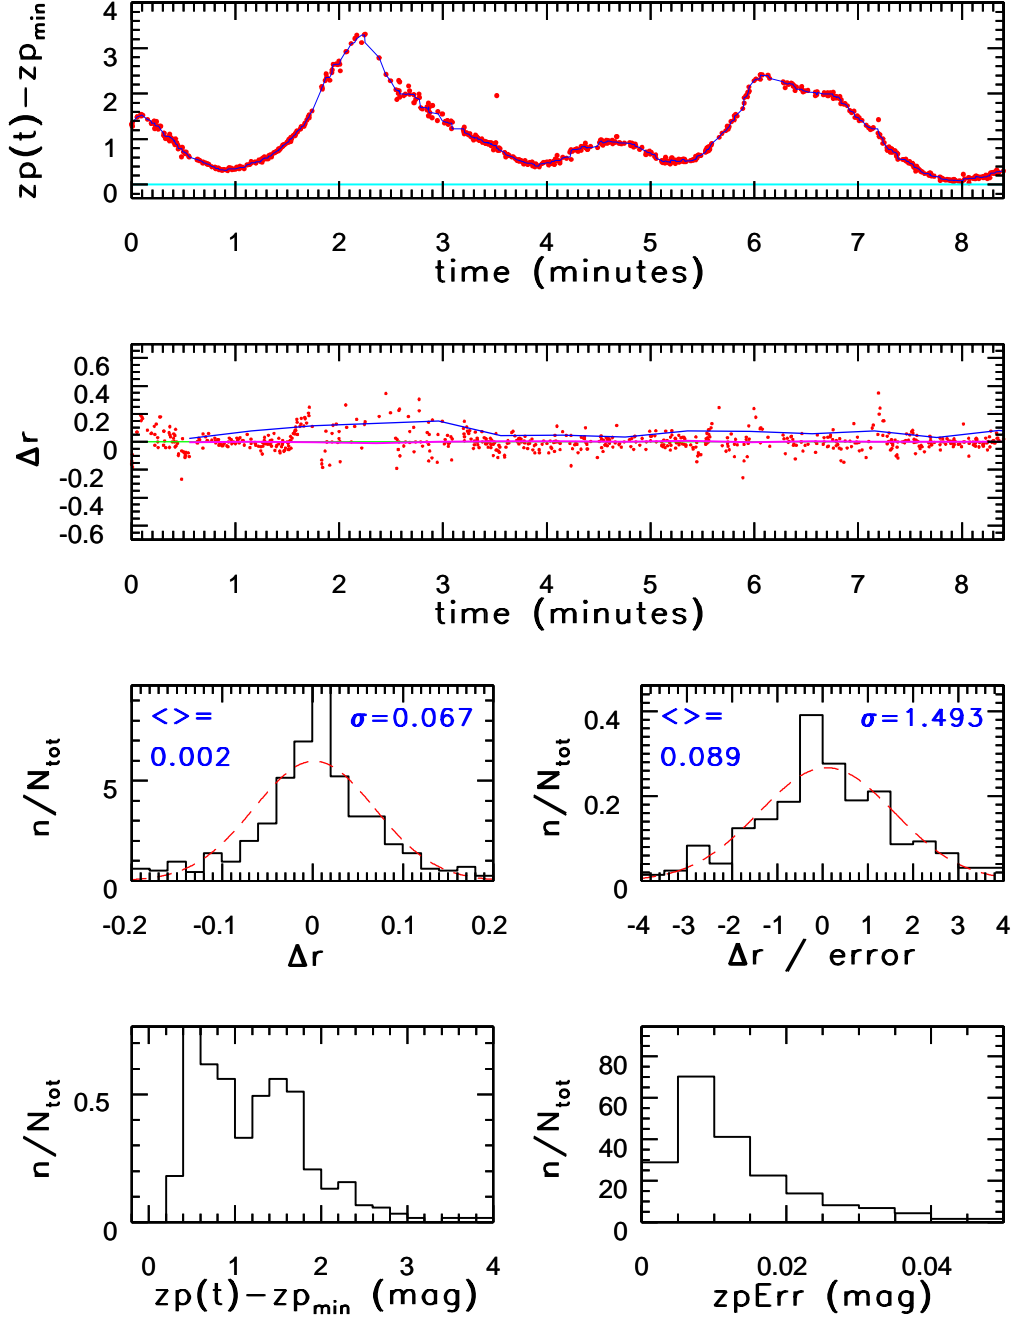

Fig. 16.— Analogous to Fig. 15, except that only ~ 8 minutes of data with large cloud extinction is shown. Note that the changes in cloud extinction are resolved down to time scales well below 1 minute.

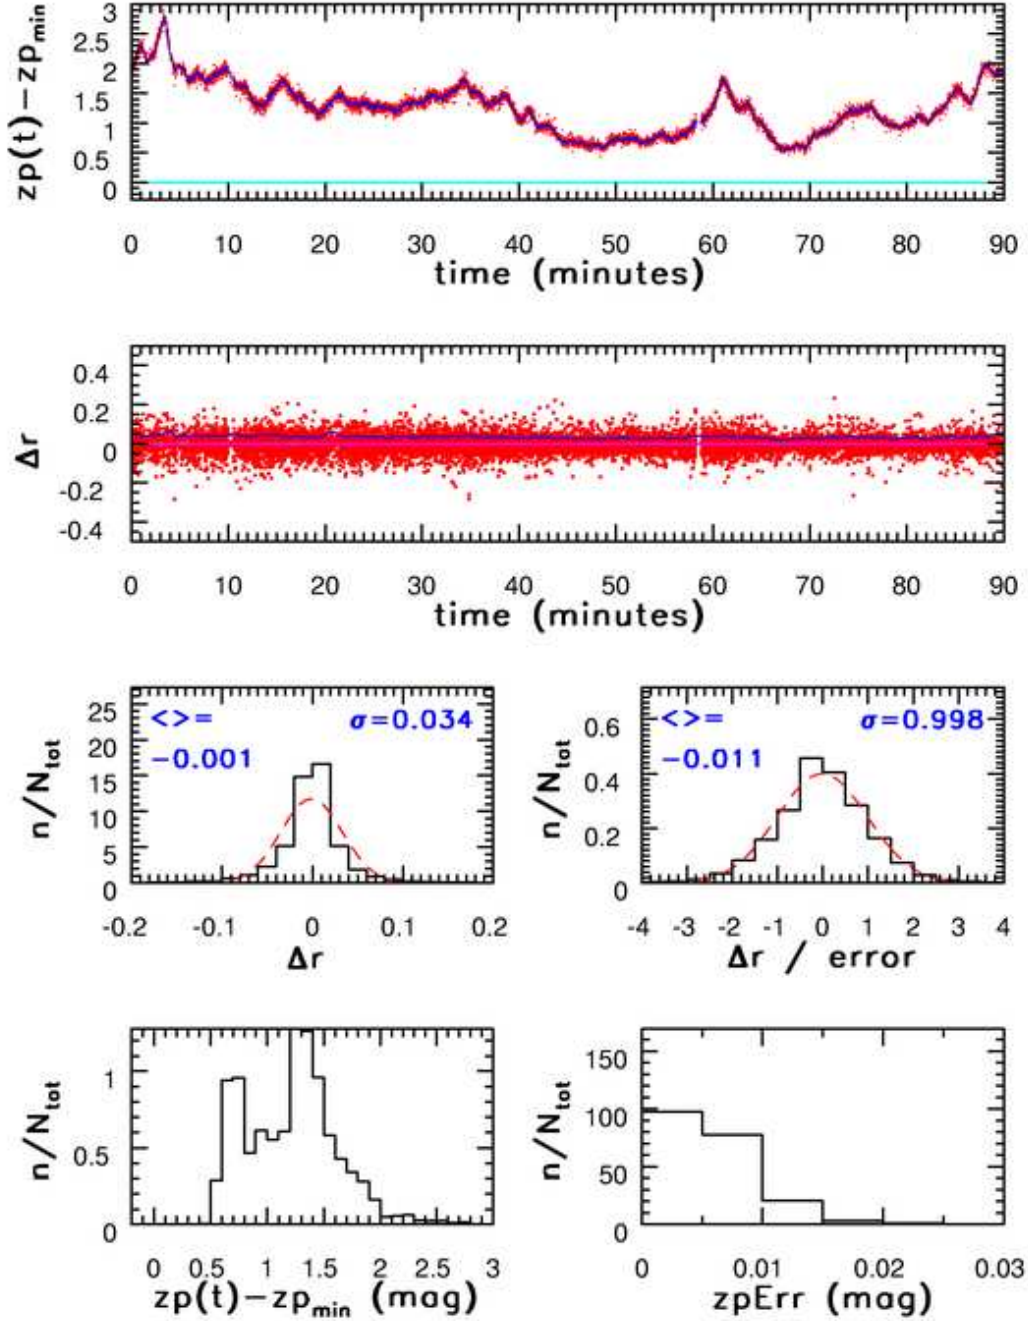

Fig. 17.— Analogous to Fig. 15, except that 1.5 hours of data from run 5759, which had somewhat thinner and much more stable cloud cover, is shown. Note that the median photometric zeropoint error is below 0.01 mag, although the median cloud extinction is larger than 1 mag.

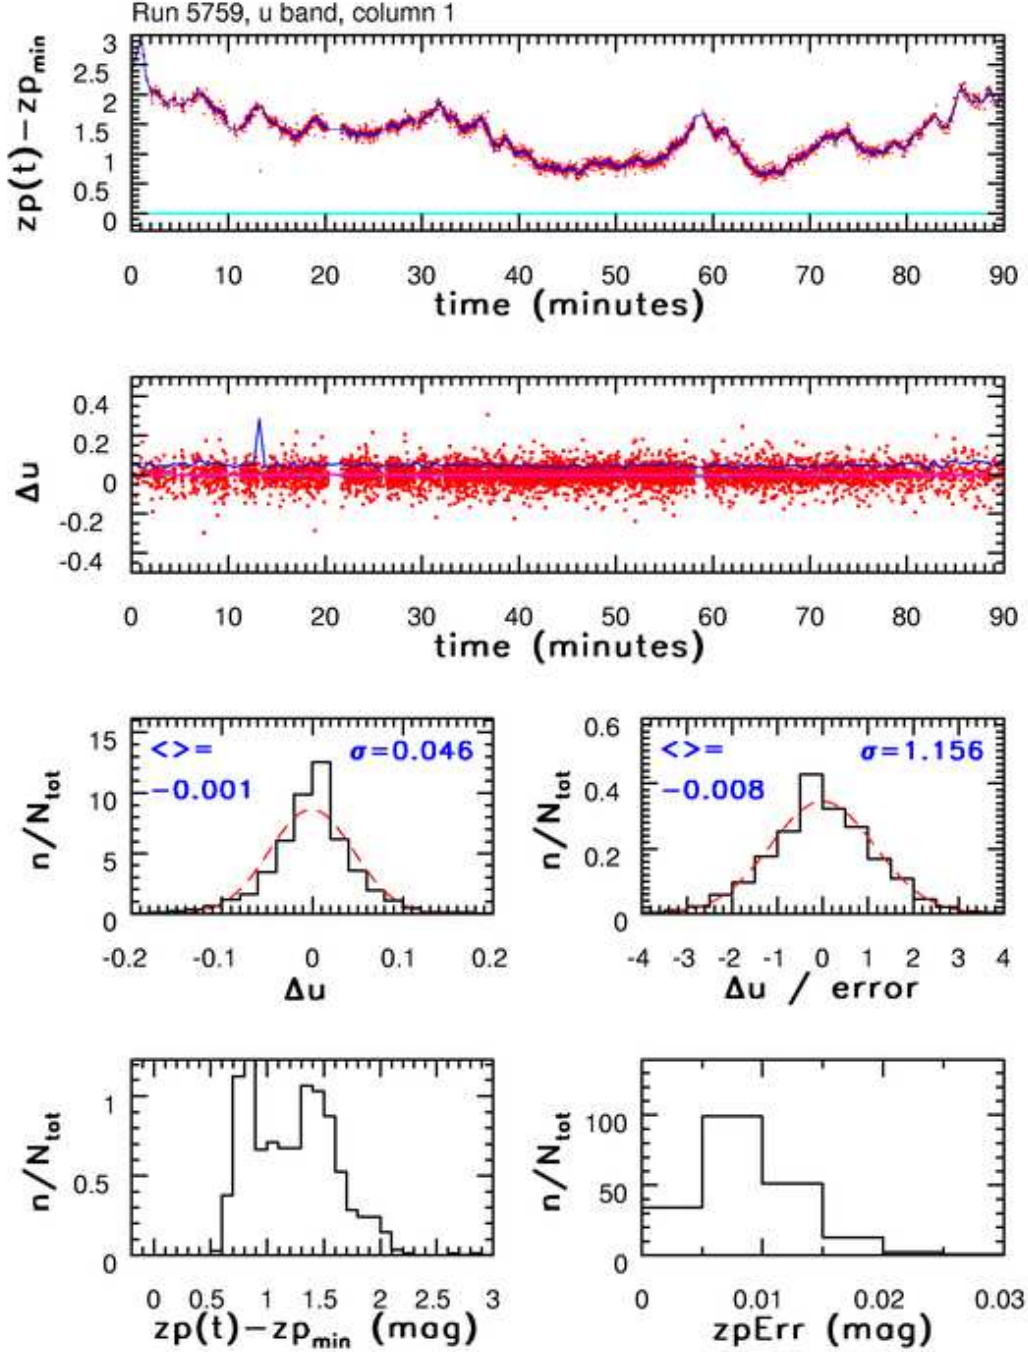

Fig. 18.— Analogous to Fig. 17, except that the u band calibration summary is shown. Despite the smaller number of calibration stars than in redder bands, and over a magnitude of cloud extinction, it is still possible to photometrically calibrate these data with a median error of only ~ 0.01 mag.

Fig. 19.— A summary of calibration accuracy as a function of the cloud extinction and band (*urz* as marked in the panels). Each small symbol represents one calibration patch (a ~ 9 arcmin² large rectangle with 1:20 aspect ratio). Zeropoint error is determined from the root-mean-scatter of photometric residuals. The large symbols show the median zeropoint error in 1 mag wide bins of cloud extinction. The left column shows data for one of the photometrically worst SDSS-II SNe runs (5646), and the right column is for a run with optically thick, but exceptionally smooth, clouds (5759). Note that the data can be calibrated with zeropoint errors typically smaller than a few percent even through clouds several mag thick.

Run 5646, column 1, implied cloud color

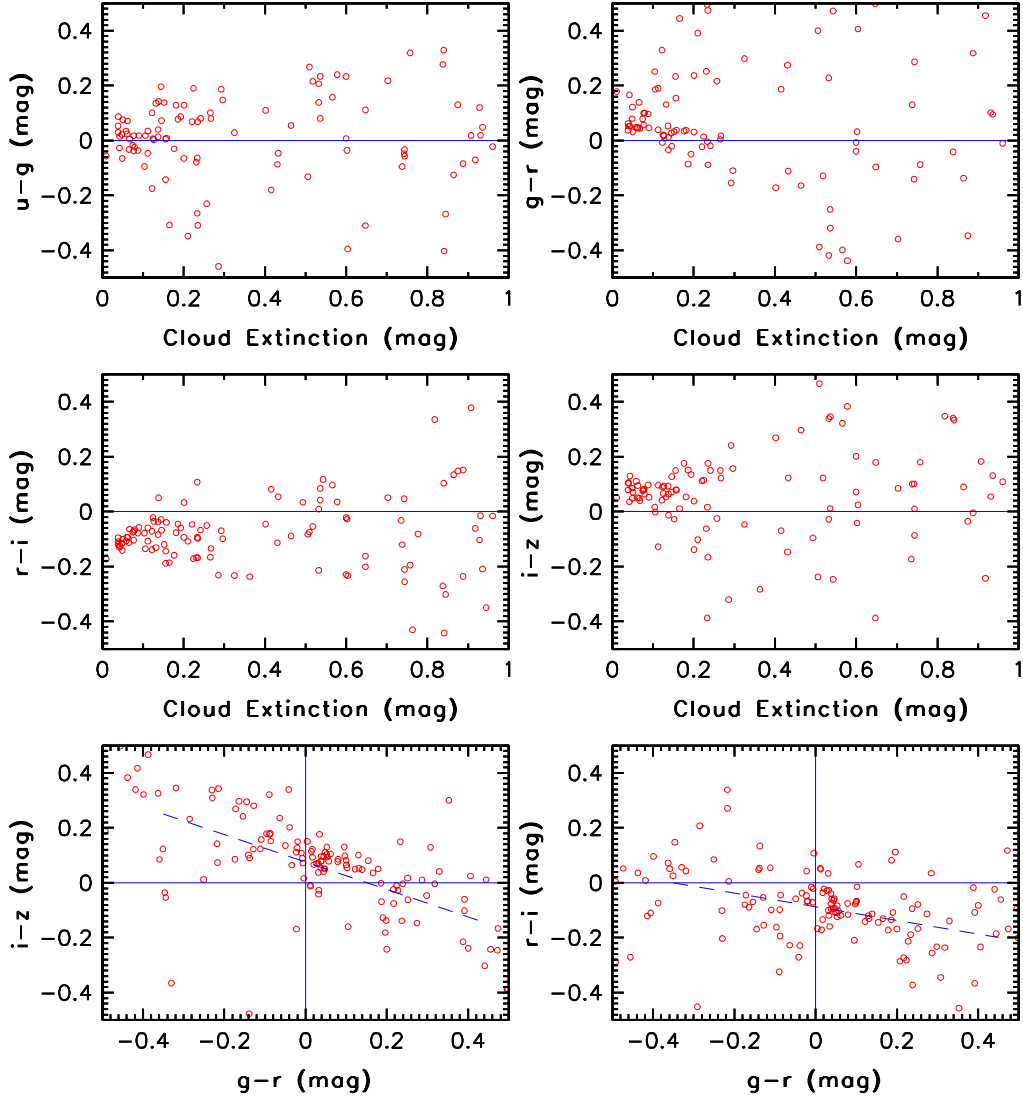

Fig. 20.— The color of cloud extinction in SDSS bands. Each symbol represents one field and shows the difference in cloud extinction between the two bands as a function of the r band extinction. The measurements in different bands are obtained over ~ 5 minutes of time and thus even gray clouds with spatially varying extinction could produce the observed non-gray (non-zero) values. The dashed lines in the bottom two panels indicate the expected correlation if the color variations are due to temporal changes in the gray cloud thickness (rather than due to intrinsic color changes).

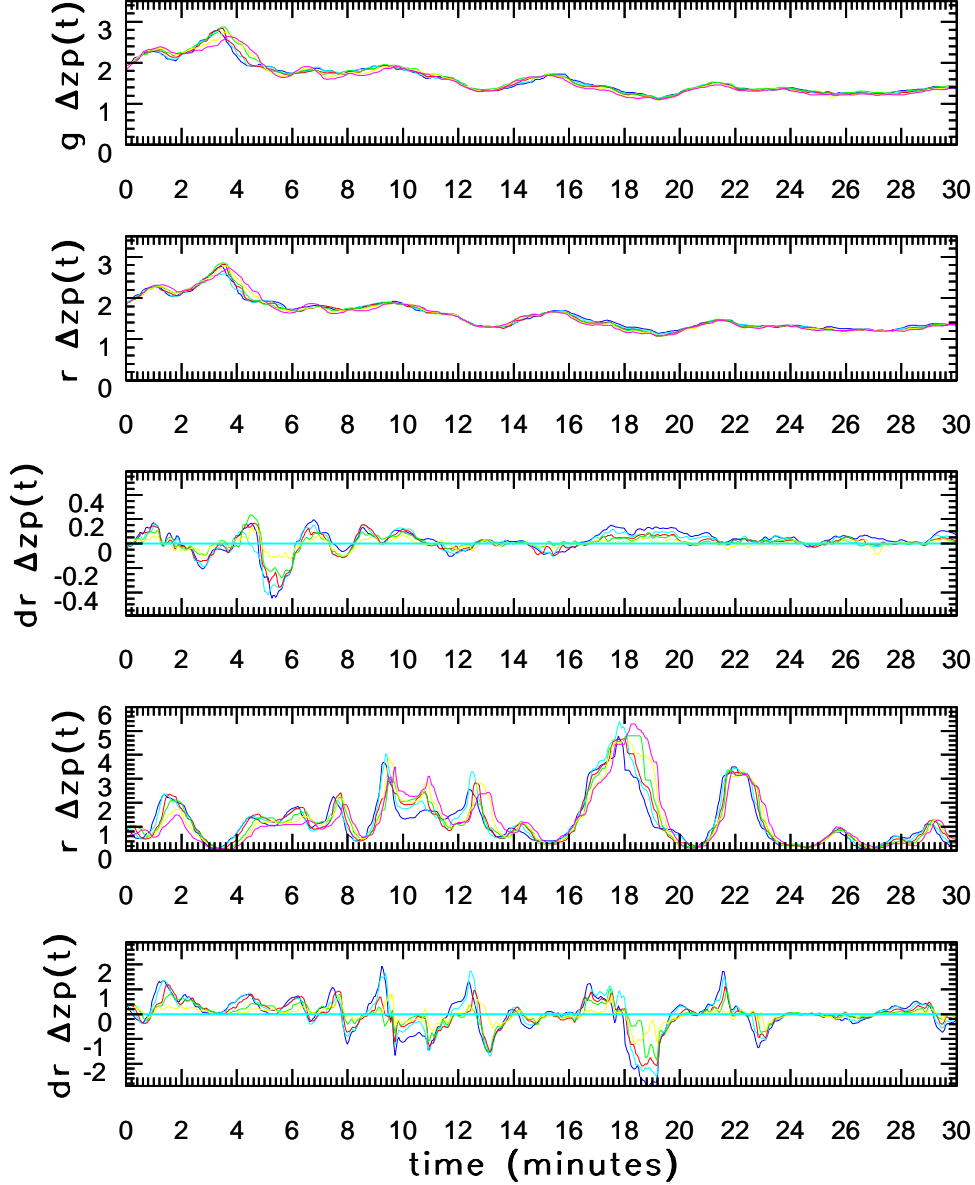

Fig. 21.— A comparison of cloud extinction independently measured for six camera columns. The top two panels show the 30 minutes of measurements in the g and r band for the same run (5759) shown in Figure 17. Individual camera columns are color-coded according to the legend shown in the top panel in Figure 6. The third panel shows the difference of the r band zeropoints measured in one of the edge columns (6) and zeropoints from other five columns. The bottom two panels are analogous to the second and third panel, except that the data are from a run with exceptionally patchy clouds (5646, the first 30 minutes of the data from Figure 15 are shown). Note the varying scale for the y axis.

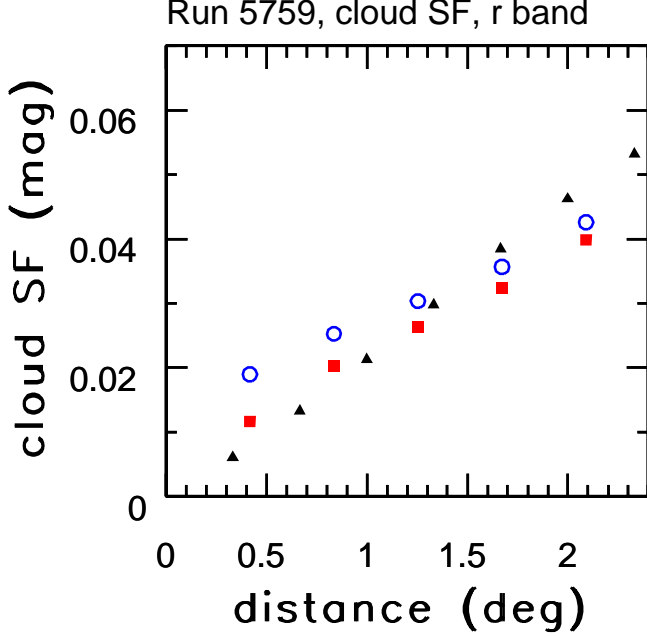

Fig. 22.— The cloud structure function in the r band for run 5759 and for the same stretch of data as shown in Figure 17 (the median cloud extinction is 1.3 mag). The circles show the rms width of the distribution of zeropoint differences between camera column 1 and (five) other columns. This width is corrected for a 0.015 mag contribution from the measurement errors and shown by squares. The triangles show the width of the distribution of zeropoint differences in the in-scan direction, with the distance scale multiplied by 30. This multiplication factor measures the cloud speed relative to the boresight in the in-scan direction (see §3.1.1).

Fig. 23.— The $g-r$ vs. $u-g$ color-color diagrams for all non-variable point sources constructed with the improved averaged photometry (dots). Various stellar models (Kurucz 1979; Bergeron et al. 2005; Smolčić et al. 2006) are shown by lines, as indicated in the figure.

Fig. 24.— An illustration of the advantages of repeated photometric measurements. The top left panel shows the blue corner of the $g-r$ vs. $u-g$ diagram from Figure 23 for *all* point sources with the averaged photometry. The top right panel shows *only* the variable sources (dominated by low-redshift quasars), and the bottom left panel shows the non-variable sources (dominated by white dwarfs), classified using low-order lightcurve moments. The bottom right panel shows the *same* non-variable sources, but using their DR5 single-epoch photometry. A comparison of the bottom two panels shows the striking improvement made possible by the use of multiple observations of the same field.
