Abstract

The MASS (Multi-Agent Spacial Simulation) library facilitates parallelization of applications that are viewed as interaction among up to millions of agents behaving over a shared virtual space and that are thus fitted to simulation of ecological, social, and physical mechanisms. The library invokes user-defined functions of all agents and array elements as well as exchanges data among them in parallel. The key to success of this library implementation is to accelerate function invocation with preprocessor-generated code and to facilitate an application debugging environment. This paper presents the design strategy, implementation, and usability of the MASS library preprocessor and debugger.

1 Introduction

Multi-agent individual-based models view computation as interaction among agents and individuals, each autonomously behaving in a shared simulation environment. They have been used for years to simulate ecological, social, and physical mechanisms that are generally difficult only with mathematical formulae. To parallelize these models, we are developing the MASS (Multi-Agent Spatial Simulation) library that updates the status of all objects at once with the callAll method and exchanges data among all objects at once with exchangeAll method. These methods are attributed as (1) one-sided parallel communication from the main function to all array elements and (2) one-sided parallel communication from each element. Therefore, MASS benefits not only multi-agent models but also data-intensive computation with its parallelization.

We implemented MASS in Java from the viewpoint of its widely used and convenient graphics features. However, due to Java’s nature as well as the multi-agents’ behavioral complexity, MASS encounters the following four challenges: (1) parallelization is killed by the slow Java reflection that is used to identify a user function called from callAll/exchangeAll; (2) exchangeAll incurs substantial communication overhead if applied to computationally fine-grained elements; (3) a programmer needs to check inter-element communication flow at an application level; and (4) agent migration is difficult to keep track of at a user level.

To address these problems, we have developed a language preprocessor and GUI-based debugger for the MASS library. The preprocessor inserts additional code in a given application for calling a user function from callAll/exchangeAll without using Java reflection and for transferring multi-element data in bulk. The debugger runs between a user application and the underlying MASS library to capture all the library calls so that it graphically shows each object’s status, monitors inter-object communication, keeps track of agent migration, and stops/resumes the user program at a break point.

This paper describes the preprocessor-assisted MASS performance improvement and library extension, presents the features and internal design of the MASS debugger, and demonstrates the uniqueness and usability of these software tools in comparison with related work.

2 MASS Library

2.1 Execution Model

Places and Agents are keys to the MASS library. Places is a multi-dimensional array of elements that are dynamically allocated over a cluster of multi-core computing nodes. Each element called a place, is pointed to by a set of network-independent array indices, and is capable of exchanging information with any other place objects. Agents are a set of execution instances that can reside on a place, migrate to any other place with array indices, and interact with other agent objects as well as multiple places.

As shown in Figure 1, parallelization with the MASS library uses a set of multithreaded communicating processes...

2.2 Library Specification

A user designs behaviors of a place and an agent by extending the Place and Agent base classes respectively, populates them through the Places and Agents classes, and performs their computation through the following methods.

**Places Class**

- **public Places( int handle, [String primitive,] String className, Object argument, int... size )** instantiates a shared array with size from className or a primitive data type as passing an argument to the className constructor. This array receives a user-given handle.

- **public Object[] callAll( String functionName, Object[] arguments )** calls the method specified with functionName of all array elements as passing arguments[i] to element[i], and receives a return value from it into Object[i]. Calls are performed in parallel among multi-processes/threads. In case of a multidimensional array, i is considered as the index when the array is flattened to a single dimension.

- **public Object[] callSome( String functionName, Object[] argument, int... index )** calls a given method of one or more selected array elements. If index[i] is not negative, it indexes a particular element, a row, or a column. If index[i] is negative, say -x, it indexes every x\(^{th}\) element. Calls are performed in parallel.

- **public void exchangeAll( int handle, String functionName, Vector<int[]> destinations )** calls from all elements a given method of all destination elements, each indexed with a different Vector element. Each vector element, say destination[i] is an array of integers where destination[i] includes a relative index (or a distance) on the coordinate i from the current caller to the callee element. The caller passes its outMessage[] data member to the callee as a set of arguments, and receives return values in its inMessage[].

- **public void exchangeSome( int handle, String functionName, Vector<int[]> destinations, int... index )** calls each of the elements indexed with index[]. The rest of the specification is the same as exchangeAll().

**Agents Class**

- **public Agents( int handle, String className, Object argument, Places places, int population )** instantiates a set of agents from className, passes the argument to their constructor, associates them with a given Places matrix, and distributes them over these places, based on map() that is defined within the Agent class.

- **public void manageAll()** updates each agent’s status, based on its latest calls of migrate(), spawn(), kill(), sleep(), wakeup(), and wakeupAll(). These methods are defined in the Agent base class and may be invoked from other functions through callAll() and exchangeAll().

2.3 Design Issues

From the user viewpoint, Places and Agents are theoretically considered as an array or a collection of Place and Agent objects respectively. However, their underlying implementation is not so simple in order to not only serve as a general simulation framework but also to work over a distributed-memory cluster. We need to address the two design challenges below:

**Language Issues:** Unless a user implements base methods of the Place or Agent class, Places and Agents do not know any methods of a user-defined class. This in turn means that the callAll/Some and exchangeAll/Some methods cannot invoke a user function simply through object casting. Instead we need to use Java reflection to interrogate a user-defined class. The problem is that the reflection works one order slower than a direct function call in general. This slow performance kills parallelization where MASS calls the same function of all objects at once. To pursue both naming flexibility and high-speed invocation of user functions, we design a Java preprocessor that inserts additional code to match the names of user functions defined in MASS methods and the actual function bodies to invoke, so that the library calls user functions without the reflection.
Debugging Issues: Since Places and Agents may be allocated over a distributed-memory cluster, the status and execution of their elements is not always visible and traceable where the main program is running. For debugging purposes, users are responsible to collect remote element status by manually inserting combinations of callAll/Some and exchangeAll/Some methods as well as adding additional graphics code into their application programs. In particular, it is tedious work for application designers to keep track of migrating Agent objects over different computing nodes. We address these debugging issues by designing a wrapper that covers the original MASS library and facilitates GUI-based debugging features.

The next two sections explain these solutions.

3 Preprocessor Design

3.1 Library Extension

We extend MASS to avoid Java reflection and to accelerate message exchange among Place objects as follows:

Eliminating Java Reflection: Given a function name in the MASS methods, we need to quickly identify its function body to invoke. A trivial but naive idea is to store user function names in a symbol table at compile time and thereafter to compare each symbol table entry with a function name specified in a MASS method each time it is invoked at run time. The problem is repetitive string comparisons that may weigh more than actual computation at each place or agent. Instead we use integer comparisons where user function names found in MASS methods receive a different integer, (i.e., a function id) at compile time and a MASS method invokes the user function corresponding to a given function id. Figure 2 shows preprocessor-generated example code that jumps from two MASS methods to a different user function: two user function names such as “exchangeArray” and “putArray” in exchangeAll() and callAll() (lines 1-2) receive a function ID respectively (lines 6-7); the original exchangeAll() and callAll() calls the preprocessor-generated callMethod() (line 12); and the control branches off to the corresponding user function, based on the function id (lines 14-15).

Exchanging Each Place’s Boundary Information: The MASS library originally assumes that a Place object is used as an individual element of a distributed array. However, the cost for exchangeAll/Some is substantial to fine-grained computation at each Place object, because data exchange generally takes place with multiple neighbors. Therefore, a user wants to include a collection of array elements in each Place object that then exchanges its boundary elements (or shadow elements) in fewer packets with neighbors as shown in Figure 3. This reduces the frequency of communication over an entire array while increasing the computation amount per Place. A new MASS library function named exchangeBulk exchanges such boundary information among neighboring Places. As shown in Figure 4, we achieve it by translating exchangeBulk into a combination of exchangeAll and callAll (lines 6-7): the former calls a given function of all neighboring Place objects to retrieve their boundary information, and the latter put the information into the local Place’s boundary space. The MASS preprocessor assumes that a user defines exchangeArray and putArray, where Array is a user-defined Place object, each actually achieving data retrieval and saving operations. If not, the preprocessor generates simple stub functions (lines 9-15). Thereafter, it converts this pair of exchangeAll and callAll into those calling the user functions with their function IDs as described in Figure 2.

3.2 Design Strategies

We design and implement the MASS preprocessor, based on the following two strategies. First, we use an existing Java compiler-compiler tools: JavaCC and JJTree.
A new MASS method to exchange boundary data

```java
myPlaces.exchangeBulk(h, Array, neighbors);
```

preprocessor-generated exchange/callAll from exchangeBulk

```java
myPlaces.exchangeAll(h, "exchangeArray", neighbors);
myPlaces.callAll(h, "putArray", neighbors);
```

```java
class ExchangeOptimizer {
    public Object exchangeArray(Object src) {
        return (Object)Array.getBoundary((int[][])src);
    }
    public Object putArray(Object arg) {
        Array.putBoundary(inMessages);
        return null;
    }
}
```

Second, we carry out two passes of MASS program translation: pass 1 converts `exchangeBulk` into a combination of `exchangeAll/callAll`, and pass 2 generates additional code to call a user function from a MASS library method with its function ID. The following details an implementation of our MASS preprocessor.

### 3.3 Implementation

The preprocessor performs its optimizations by running the input code through a Java parser. The parser emits tokens in response to the input code. Actions are taken on specific tokens to check conditions, set flags, and modify output. A grammar defines a roughly correct version of Java. It has been modified to create Abstract Syntax trees. From the grammar, a parser is generated (as UnparseVisitor.java) which by default will output any input which matches the Java language as defined by the grammar. As shown in Figure 5, the parse methods can be overwritten with MASSOptimizer, ExchangeBulkOptimizer, or ReflectionOptimizer to perform MASS optimizations. For example, when parsing a `MethodDeclaration` token, a flag will be set to indicate that a new method is being parsed and that a new scope must be placed on the stack. Subsequently, if a `ResultType` token is parsed while the `MethodDeclaration` flag remains set, the return type of the parsed method can be recorded. These optimizers in Figure 5 set flags in their `visit()` methods and implement the logic to respond to those conditions in their `find(Token)` methods.

The preprocessor has been tested on some MASS programs including two-dimensional wave simulation (Wave2D) and three-dimensional computational fluid dynamics (CFD). The verification and performance evaluation has been conducted by comparing manually-translated versus preprocessor-generated code. Figure 6 demonstrated the competitive performance of preprocessor-generated code in Wave2D and CFD when running the code four times on a 64-bit 2.27GHz Intel Core.

### 4 Debugger Design

A simple debugging program was implemented to assist MASS developers. Currently, the debugger uses the multithreaded Java version of MASS. It allows users to view a logical arrangement of their computational spaces’ values through a 2D or 3D graphical view.

#### 4.1 Debugging Features

The basic objective of the debugger is to display the contents of computational nodes in a human-understandable format, as shown in Figure 7. Its features are designed to support this goal:

- Displays results in a flat view or hawk’s eye view.
- Opens windows to display additional dimensionality.
- Allows debugging in code or in GUI.
- Sets break points and defines iteration points.
- Advances to next break point or by iteration.
- Shows communication between logical nodes.
- Saves and restores computational values.

The developer can set break points in program iteration. This differs from traditional debugging code break points, and is more akin to setting break points based on variable values. However, the developer can specify when in the driving code that an iteration occurs, allowing a more fine-grained approach than might be initially apparent.
4.2 Design Strategies

Design of the debugger followed a twofold strategy. The debugger wraps functions of the MASS class library as shown in Figure 8, and development is driven by the need for features to show information in terms of the MASS application developer’s perspective. The development of the debugger relied on an iterative approach that focused on design, planning, and prioritization of features. A basic goal is to implement features as simply as possible. Early in the process it became apparent that there were two challenges: accessing MASS and creating the graphical interface. Comparing the two, using MASS was simpler than creating the graphics, but had yet to be thoroughly explored. The debugger is the first application to demonstrate that multiple classes can utilize MASS concurrently.

4.3 Implementation

The debugger program exists separately from the MASS library. Therefore, it is not affected by changes in the MASS implementation that don’t affect MASS function signatures. In effect, it serves as an intermediary layer that wraps MASS functions. In addition to the debugger class, there are classes for graphical control objects: the display windows and buttons. When data is returned from the MASS classes, in addition to returning the data to the user, the debugger also instantiates graphical objects using Java’s awt classes, and displays the results. The organization of the results are based on the user-defined sizes of the arrays that are passed to MASS when it is initialized. In this context, the implementation of the debugging features only has to use simple private counters and Booleans to keep track of iterations and breakpoints. When a breakpoint is hit, further function calls to MASS are suspended. Since all MASS results are returned in single arrays, there is no latency in updating individual node results from the debugger or user perspective. Depiction of exchange results are more difficult, because MASS does not provide return values for them. The user provides a vector of relative node coordinates where data is exchanged. The debugger applies the vector to each computational node to determine the coordinates where the data exchange occurred, and shows the last computation (from a MASS CallAll function) as the data that is sent. Checkpoints take the return values from a computation and store them in a file. The file is read back into an array of objects when the checkpoint is restored, and passed to MASS. It is important to note that this method of restoring a checkpoint is only valid if the user’s places do not rely on local resources, such as a local system clock, for their calculations. The debugger offers three general types of public methods, as shown in the sample code of a simple driver application in Figure 9:

- MASS-equivalent functions with identical signatures
- MASS-equivalent functions with extended signatures for the debugger
- Debugger-only functions, such as setting break points.
The MASS functions with extended signatures combine MASS-equivalent functions with debugger functions, trading fewer function calls for ones with more parameters. Control buttons also implement debugger functions for features such as advancing one iteration or continuing to the next break point while the user’s program is running.

```java
// Initialization of MASS through debugger
detector.debugIterateCallAll(0, (Object[]) null);
// (ticks iterator shows results in GUI)
detector.debugCallAll(0, (Object[]) null);
// MASS-equivalent function with debugger parameters
while (!detector.isFinished()) {
    // Use of MASS through debugger
    if (detector.isFinished()) {
        // Pure debugger functions
        detector.setStopOnBreakPoint(true);
        detector.setBreakPoint(20);
        detector.setTotalIterations(iterations);
        // Initialization of MASS through debugger
        debugger.debugIterateCallAll(0, (Object[]) null);
        // Pure debugger functions
        debugger.setStopOnBreakPoint(true);
        debugger.setBreakPoint(20);
        debugger.setTotalIterations(iterations);
        // MASS-equivalent function called through debugger
        detector.debugCallAll(0, (Object[]) null);
        // MASS-equivalent function called through debugger
        debugger.debugIterateCallAll(0, (Object[]) null);
        // ...with iteration set separately
        debugger.iterate();
        // MASS function with debugger parameters
        // (ticks iterator shows results in GUI)
        debugger.debugIterateCallAll(0, (Object[]) null, true);
    }
}
// end debugger operations and clean up graphics
```  

Figure 9. Code using debugger; breakpoint set for every 20 iterations

5 Related Work

5.1 Preprocessors

Our MASS library and preprocessor design involves library-assisted parallel execution, preprocessor-assisted code generation, and code manipulation. Those techniques are found in the following four language systems.

Parallel Java Library promotes hybrid SMP cluster programming in Java by combining multithreaded programming constructs and MPI-based message-passing functions [4]. MASS and Parallel Java libraries both take a similar approach in hiding all underlying parallelization work with their Java library classes and methods. However, the major difference is that MASS does not distinguish shared and distributed memory but gives a consistent view of multi-agents running on a shared array regardless of underlying memory architectures.

Extensible PreProcessor (EPP) defines plug-ins for generating tiny data-parallel Java code [3], where the special modifier “parallel” given to a Java class generates additional multithreading code in its run() method that handles all data with virtual processors in parallel. Although MASS and EPP use a preprocessor approach for parallelization, EPP focuses on multithreading, whereas the MASS preprocessor extends its scope to hybrid SMP cluster computing.

MPIPP is another preprocessor tool that converts a user-defined data structure into MPI-derived data types [6]. It is similar that our exchangeBulk() function converts a certain range of boundary array elements to Place.outMessage as well as Place.inMessages back to the original elements. However, our MASS preprocessor is different in generating get() and put() methods to automate entire boundary-to-boundary element transfers.

Javassist facilitates a compiler-assisted Java bytecode manipulation that defines new classes, freezes existing classes, and customizes class members [1]. Therefore, Javassist can works as another option to optimize the exchangeBulk() function and to match user function names in the MASS library and their actual function bodies, by directly manipulating a user program. However, it would be the same amount of work required if our preprocessor were redesigned to introspect and manipulate all MASS keywords with Javassist.

5.2 Debuggers

The MASS debugger is a framework-oriented, library-based, visualization-focused, and data-parallel application debugger. In these categories, we found similarities to and differences from the following four products.

Hadoop and the MASS debugger are both framework-oriented debugging utilities. Hadoop uses a Java class based on the JUnit3 test case and performs testing using a virtual map cluster [8]. The MASS debugger debugs through the actual execution of the MASS program, as MASS controls where its computational spaces run. Hadoop Test Case output is console output, shown through the user’s IDE. MASS debugger output uses its own graphical interface.

MPI Debugging Interface is used to provide the conceptual message passing state of the program [2]. The debugger implementation studies the communicator queues; the MASS equivalent of these are the parameters of its major functions. Both applications conclude that accessing the library class must be led by the debugger. Specific interfaces to display data are not implemented by the MPI debugger in contrast to the MASS debugger’s GUI.

TotalView is a feature-heavy, commercial debugging interface designed for distributed software [7]. TotalView, like MASS, makes use of a GUI for data visualization but lacks concurrent display of values. The TotalView software is more sophisticated than MASS but also more complicated, and is not free. MASS, in contrast, is geared specifically to MASS users and is currently free. Using TotalView with MASS would strip away all the abstraction that the
MASS library is providing.

Global Arrays are a means to solve data-parallel jobs, and intersects with MASS’s application areas [5]. It gives the user very fine-grained control over the data objects it uses, but at the cost of a great deal of programming complexity in implementation. In contrast, MASS aims explicitly to simplify and abstract away complexity. Global Arrays do not in themselves provide explicit debugging tools; while the MASS debugger is an extension of MASS that does not currently exist in Global Arrays.

In summary, we believe that our design strategy for the MASS preprocessor and debugger fits user requirements for multi-agent spatial simulation.

6 Future Work

6.1 Preprocessor

At present our preprocessor has the following limitations and issues: (1) MASS applications to be processed should not contain a method named “callMethod” or use a trailing underscore (“_”) as part of a method name; (2) all methods to be called from callAll/Some or exchangeAll/Some must accept the same set of parameters in the same order; (3) user-owned non-MASS methods should not have names identical to MASS methods; and (4) MASS variables may not be recognized if they are cast or assigned to other classes at runtime. We believe that these limitations are acceptable.

As our future work items, we are developing C, C++, and CUDA-C versions of the MASS library. Since C and C++ allow programmers to use dynamic linking and function pointers, we do not see any necessity of developing a MASS preprocessor for them. However, CUDA-C has its own extensions to C. Although these extensions are quite unique to GPUs, we are planning to develop a preprocessor that assists C programmers in running MASS applications on GPUs. Our ultimate goal is to facilitate a Java or C++ version of the MASS library for GPU computation through a cascading code translation to CUDA-C.

6.2 Debugger

Currently, the MASS debugger focuses on the step-by-step display of computational node data and communication. The limitations include: (1) agents and their migration are not displayed; (2) the interface is still only a proof-of-concept design; (3) break points are not based on computational node values; and (4) analysis and step-through of the developer code itself is not implemented.

Implementation of agent status and migration view is the immediate next step in terms of future development. The interface must be improved for the overall user experience. Allowing break points based on computational node values will give the user more flexibility. However, the goal of the MASS debugger is to provide an easy way to view MASS computations, not to become a commercial debugger with a full feature set. Consequently, certain debugger features: the ability to step through code and to set break points in the code itself, are not prioritized for future development.

7 Conclusions

The MASS library eases parallelization of multi-agent individual-based models as well as data-intensive applications. In this paper, we analyzed the current issues in code development and execution with the library, addressed them with our preprocessor approach and debugger design. The MASS library and tools will be made available upon an email request sent to dslab@uw.edu.
