ABSTRACT

We introduce a microscopic model of a lipid with a charged headgroup and flexible hydrophobic tails, a neutral solvent, and counter ions. Short-ranged interactions between hydrophilic and hydrophobic moieties are included as are the Coulomb interactions between charges. Further, we include a short-ranged interaction between charges and neutral solvent, which mimics the short-ranged, thermally averaged interaction between charges and water dipoles. We show that the model of the uncharged lipid displays the usual lyotropic phases as a function of the relative volume fraction of the headgroup. Choosing model parameters appropriate to dioleoylphosphatidylethanolamine in water, we obtain phase behavior that agrees well with experiment. Finally we choose a solvent concentration and temperature at which the uncharged lipid exhibits an inverted hexagonal phase and turn on the headgroup charge. The lipid system makes a transition from the inverted hexagonal to the lamellar phase, which is related to the increased waters of hydration correlated with the increased headgroup charge via the charge-solvent interaction. The polymorphism displayed upon variation of pH mimics that of the behavior of phosphatidylserine.

INTRODUCTION
Biological lipids in solution display several different lyotropic phases, and the implications this may have for biological function has been a subject of speculation for many years (Cullis et al., 1985; de Kruijff 1997). Lipid phase behavior depends upon several factors, some of which are intrinsic to the lipid architecture itself. For example, an increase in the length of the hydrocarbon tails brings about transitions from lamellar, $L_\alpha$, to inverted hexagonal, $H_{II}$, phases (Seddon, 1990), whereas an increase in the volume of the headgroup brings about the reverse (Gruner, 1989). Other factors regulating phase behavior are externally controlled, such as temperature, solvent concentration, and solvent pH (Hope and Cullis, 1980; Seddon et al., 1983; Bezrukov et al., 1998). It is these factors that are the focus of this paper.

Lipid phase behavior has been addressed extensively by the construction of phenomenological free energy functions, which contain terms describing, inter alia, bending, hydration, and interstitial energies (Helfrich, 1973; Kirk et al., 1984; Rand and Parsegian, 1989; Kozlov et al., 1994). Such approaches, which obtain their several parameters from experimental measurement of various quantities, are quite useful, particularly in correlating phase behavior with other thermodynamic properties. Nonetheless, it would clearly be desirable to derive all thermodynamic quantities, including the phase behavior, by applying statistical mechanics to a microscopic model of the system. In addition to simplifying the description considerably, such approaches would correlate phase behavior with the architectural properties of the lipid itself and its solvent.

Analytic, mean-field approaches of statistical mechanics have been applied to anhydrous lipids to investigate behavior of increasing complexity. Such methods have been combined with realistic models of lipid tails to determine how the hydrocarbon chains pack in aggregates and in bilayers (Marcelja, 1974; Gruen, 1981; 1985; Ben-Shaul et al., 1985; Fattal and Ben-Shaul, 1994). Results for the bilayer are in good agreement with molecular dynamic simulation (Tieleman et al., 1997). These methods have shown that, in a neutral, anhydrous system, the entropy of the lipid tails always favors the $H_{II}$ over the $L_\alpha$ phase, and that a change in area per headgroup could bring about a transition between them (Steenhuizen et al., 1991).

Aggregates, such as the lipid bilayer, in the presence of solvent have also been considered within the mean-field approach applied to lattice models (Leermakers and Scheutjens, 1988). In addition to the tails, one must now model the solvent and the headgroups, and phosphatidylcholine and phosphatidylserine headgroups are among those that have been described (Meijer et al., 1994). The method is flexible and has been applied to many different systems, including bilayers with trans-membrane guest molecules (Leermakers et
al., 1990). Results are quite good, with the exception that the local volume fraction of solvent inside the bilayer is rather large, several orders of magnitude greater than that observed in experiment (Jacobs and White, 1989). Lattice models, however, are not well-suited to the description of transitions between phases of different symmetry.

It would be extremely useful to have available a relatively simple and tractable model of lipids that was capable, at least, of describing the effect of their architecture upon their phase behavior. With this in hand, one could, inter alia, examine the various bicontinuous phases to determine their stability or metastability (Shyamsunder et al., 1988), and to explicate the reasons they facilitate the crystallization of membrane proteins (Landau and Rosenbusch, 1996). Further, one could explore mixtures of lamellar- and nonlamellar-forming lipids to determine the role that the latter play in lipid-protein interactions (Epand, 1998), membrane fusion (Markin et al., 1984; Siegel, 1993), and membrane function (Hui, 1997), all areas in which the importance of their presence has been indicated.

Toward this end, a model system of solvent and monoacyl lipid embedded in a continuous space was recently introduced. Its phase diagram was obtained by solving the mean-field theory exactly (Müller and Schick, 1998). It displayed both $L_\alpha$ and $H_{\Pi}$ phases, so that the transition between them could be studied as a function of lipid architecture. The dependence of the transition on the architectural parameters, length of tail, and volume of headgroup, was that observed in experiment. However, the fraction of solvent within the bilayers was again too large.

In this paper, we use a model of a lipid computationally more tractable than that used by Müller and Schick: one whose hydrocarbon tails are modeled as flexible chains rather than within the rotational isomeric states framework used earlier (Flory, 1969; Mattice and Suter, 1994). We first study the model with an uncharged headgroup. Its phase behavior, both with respect to variations in architecture and in solvent concentration, is as expected, and in agreement with experiment. In particular, choosing model parameters appropriate to dioleoylphosphatidylethanolamine (DOPE), we obtain a phase diagram similar to that observed (Gawrisch et al., 1992; Kozlov et al., 1994). We extract the variation with temperature and solvent concentration of the lattice parameter of the inverted hexagonal phase, and compare it to experiment (Tate and Gruner, 1989; Rand and Fuller, 1994). The agreement is excellent. We also find that the concentration of solvent within the bilayer is vanishingly small. We then allow the headgroup to be negatively charged. We introduce counter ions into the system, include the Coulomb interaction between all charges, and also a short-ranged interaction between charges and neutral solvent, an interaction that models the thermally averaged interaction between charges and the dipole of water. As the charge on the headgroup is turned on, the $L_\alpha$ phase is stabilized with respect to the $H_{\Pi}$. In effect, as
the charge on the headgroup increases, so too do the waters of hydration. In addition, the counter ions that are attracted to the headgroup are also enlarged by their own waters of hydration. It is the totality of these waters that effectively increases the headgroup volume and therefore stabilizes the lamellar phase.

The paper is organized as follows. In the next section, we introduce the model for the charged lipid, the solvent, and counter ions, specify all the interactions between them, and set up the partition function of the system. In the Theory section, we first derive the self-consistent field theory for it. At the heart of the theory are four self-consistent equations for the electrostatic potential of the system and the three effective fields that determine the headgroup, tail, and solvent densities. One of these self-consistent conditions is simply the nonlinear Poisson-Boltzmann equation. We then expand all functions of position into a complete set of functions having a specified space-group symmetry, and rewrite the self-consistent equations in terms of the coefficients of these expansions. These equations are solved numerically, and the free energies of the various phases computed. A comparison of the free energies yields the phase diagram.

In the Results section, we first present the phase diagram for the neutral lipid as a function of temperature and one architectural parameter. We include here only the classical phases, lamellar, inverted and normal hexagonal, and inverted and normal body-centered-cubic, as well as the disordered phase. For the remainder of this subsection, we choose an architecture such that the anhydrous, neutral lipid orders into the $H_{II}$ phase. Results for the system in the presence of a neutral solvent, along with comparisons to experiment, are presented next.

In the next subsection, we consider the charged lipid. We choose a water concentration such that the neutral lipid remains in the $H_{II}$ phase. By varying the counter ion concentration, we turn on the charge on the headgroup, and thus all Coulomb interactions, and all short-ranged interactions between charges and solvent. We find that the $L_{\alpha}$ is indeed stabilized with respect to the $H_{II}$ phase, in agreement with experiment (Hope and Cullis, 1980; Bezrukov et al., 1998).

> **THE MODEL**

We consider a system composed of charged lipids, neutral solvent, and counter ions in a volume $V$. There are $n_L$ lipids, each of which consists of a head, with volume $v_h$, and two equal-length, completely flexible tails each consisting of $N$ segments of volume $v_t$. Each lipid tail is characterized by a radius of gyration $R_g = (Na^2/6)^{1/2}$, with $a$ the statistical segment
length. The heads carry a negative charge $-eQ_h$. The solvent consists of $n_s$ neutral particles of volume $v_s$, whereas the $n_c$ counter ions have charge $+e$ and negligible volume, $v_c = 0$. There are five dimensionless densities that totally specify the state of the system; the number density of the headgroups, $\Phi_h$, of the tail segments, $\Phi_t$, and of the solvent, $\Phi_s$, and the charge density of the headgroups, $\Phi_{h}'$, and of the counter ions, $\Phi_{c}'$. They can be written as

$$\Phi_h(r) = v_h \sum_{l=1}^{n_h} \delta(r - r_l(1/2)), \quad (1)$$

$$\Phi_t(r) = v_h \sum_{l=1}^{n_t} \int_0^1 \delta(r - r_l(s)) \, ds, \quad (2)$$

$$\Phi_s(r) = v_h \sum_{j=1}^{n_s} \delta(r - R_{s,j}), \quad (3)$$

$$\Phi_{h}'(r) = -v_h \sum_{l=1}^{n_h} Q_{h,l} \delta(r - r_l(1/2)), \quad (4)$$

$$\Phi_{c}'(r) = v_h \sum_{i=1}^{n_c} \delta(r - R_{c,i}). \quad (5)$$

We have chosen $v_h$ as a convenient volume to make all densities dimensionless. In the above, $R_{s,j}$ is the position of the $j$th solvent particle, and $R_{c,i}$ the position of the $i$th counter ion. The configuration of the $l$th lipid is described by a space curve $r_l(s)$, where $s$ ranges from 0 at the end of one tail, through $s = 1/2$ at which the head is located, to $s = 1$, the end of the other tail. The nominal probability that the charge on the headgroup of the $l$th lipid, $-eQ_{h,l}'$, is equal to $-e$ or 0 is $p$ or $1 - p$, respectively. As we model the case in which charges can associate or dissociate from the headgroup, it will be necessary to average the partition function of the system with respect to the charge distribution. This corresponds to an annealed distribution in the nomenclature of Borukhov et al. (1998). The concentrations of lipid, solvent, and free counter ions are controlled by chemical potentials. In particular, increasing the number of free, positive, counter ions implies, by charge neutrality, an increase in the negative charge on the headgroups, and thus corresponds to an increase in the
The pH of the system.

The interactions among these elements are as follows. First, there is a repulsive, contact interaction between headgroup and tail segments, and also between solvent and tail segments. The strength of the interaction is \( k T \chi_h \), where \( k \) is Boltzmann’s constant and \( T \) the absolute temperature. Second, there is the Coulomb interaction between all charges. The dielectric constant of the solvent is denoted \( \varepsilon \). Finally, there is a contact interaction between all charges and the neutral solvent, whose strength is \( k T \lambda \). This is to model the short-ranged, thermally averaged interaction between charges and the dipole of water, an attractive interaction that decreases like \( r^{-4} \) and is of strength \( e^2 u^2 / 6 \varepsilon^2 kT \), where \( u \) is the dipole moment of water (Israelachvili, 1985). Thus, the energy per unit volume of the system, \( E/V \), can be written

\[
\frac{v_h}{kT} \frac{E}{V} [\tilde{\Phi}_h, \tilde{\Phi}_t, \tilde{\Phi}_s, \tilde{P}_h, \tilde{P}_c]
\]

\[
= 2\chi N \int \frac{dr}{V} [\tilde{\Phi}_h(r) + \tilde{\Phi}_s(r)]\tilde{\Phi}_t(r)
\]

\[
+ \frac{\beta^*}{8\pi} \int \frac{dr}{V} \frac{dr'}{R_g^2} [\tilde{P}_h(r) + \tilde{P}_c(r)] \frac{1}{|r - r'|} [\tilde{P}_h(r') + \tilde{P}_c(r')]
\]

\[
- \lambda \int \frac{dr}{V} \tilde{\Phi}_s(r) [\tilde{P}_c(r) - \tilde{P}_h(r)],
\]

where

\[
\beta^* \equiv \frac{4\pi e^2 R_g^2}{v_h \varepsilon kT}
\]

is a dimensionless measure of the strength of the Coulomb interaction. The grand partition function (Matsen, 1995) of the system is

\[
Z = \sum_{n_1, n_c, n_s} \frac{z_1 z_c z_s}{n_1! n_c! n_s!} \int \prod_{l=1}^{n_1} dR_l \prod_{i=1}^{n_c} dR_{c,i} \prod_{j=1}^{n_s} dR_{s,j}
\]

\[
\times \exp \left\{ -E[\tilde{\Phi}_h, \tilde{\Phi}_t, \tilde{\Phi}_s, \tilde{P}_h, \tilde{P}_c] / kT \right\} \delta(1 - \tilde{\Phi}_h - \gamma_s \tilde{\Phi}_s - \gamma_t \tilde{\Phi}_t).
\]
Here, $\int \tilde{\mathbf{r}}_l$ denotes a functional integral over the possible configurations of the $l$th lipid and in which, in addition to the Boltzmann weight, the path is weighted by the factor $\mathcal{P}[r_{l,1}(s); 0, 1]$, with

$$\mathcal{P}[r, s_1, s_2] = \mathcal{N} \exp \left[ -\frac{1}{8R_g^2} \int_{s_1}^{s_2} ds \left| \frac{dr(s)}{ds} \right|^2 \right], \quad \text{(9)}$$

with $\mathcal{N}$ an unimportant normalization constant. The notation $\int \delta Q_{h,l}$ denotes an integral over the probability distribution of the charge on the headgroup of the $l$th lipid. We have enforced an incompressibility constraint on the system with the aid of the delta function $\delta(1 - \hat{\Phi}_h - \gamma_s \hat{\Phi}_s - \gamma_t \hat{\Phi}_t)$, where $\gamma_s = v_s / v_h$, and $\gamma_t = 2Nv_t / v_h$. The latter parameter is the lipid architectural parameter. The relative volume of the headgroup with respect to that of the entire molecule is $1/(1 + \gamma_t)$.

The model is now completely defined. The solvent is specified by $\gamma_s$, its volume per particle relative to that of the headgroup, and the architecture of the lipid is characterized by $\gamma_t$.

There are three interactions, hydrophobic-hydrophilic, charge-charge, and charge-solvent, whose strengths are given by $\chi$, $\beta^*$, and $\lambda$, respectively. The external parameters are the temperature, conveniently specified in terms of a dimensionless temperature $T^* \equiv (2\pi N)^{-1}$, the fugacity of the solvent, $z_s$, and the fugacity of the free counter ions, $z_c$, which, by charge neutrality, controls the charge on the lipid headgroups. The characteristic length in the system is the radius of gyration, $R_g$. In the next section, we derive the self-consistent field theory for the model, first in real space, and then in Fourier space.

**THEORY**

**Real space**

Evaluation of the partition function of Eq. 8 is difficult because the interactions are products of densities, each of which depends on the specific coordinates of one of the elements of the system. This dependence is eliminated in a standard way. We illustrate it on $\Phi_h(\mathbf{r})$ which, from its definition in Eq. 1, depends on the coordinates of the headgroup, $\mathbf{r}_l(1/2)$. One introduces into the partition function the identity

$$1 = \int \mathcal{D}\Phi_h \delta(\Phi_h - \hat{\Phi}_h), \quad \text{(10)}$$
in which $\Phi_h(r)$ does not depend on any specific coordinates of one of the elements of the system, but is simply a function of $r$. The integration on $W_h$ extends up the imaginary axis. Inserting such identities for the five densities $\tilde{\Phi}_h$, $\tilde{\Phi}_t$, $\tilde{\Phi}_s$, $\tilde{P}_h$, and $\tilde{P}_c$, and a similar identity for the delta function expressing the incompressibility condition, one rewrites the partition function, Eq. 8, as

$$Z = \int D\Phi_h D\Phi_t D\Phi_s D\Phi_c D\Phi_h D\Phi_t D\Phi_s D\Phi_c D\Phi_h D\Phi_t D\Phi_s D\Phi_c \exp \left\{ -E[\Phi_h, \Phi_t, \Phi_s, P_h, P_c]/kT \right\}$$

$$\times \exp \left\{ \frac{1}{v_h} \int \left[ W_h \Phi_h + W_t \Phi_t + W_s \Phi_s + U_h P_h + U_c P_c + \Xi(1 - \Phi_h - \gamma_s \Phi_s - \gamma_t \Phi_t) \right] dr \right\},$$

where

$$Q_i[W_h, W_t, U_h] = \int D\gamma_1 D\gamma_2 Q_h \exp \left\{ -W_h \left( \gamma_1 \left( \frac{1}{2} \right) \right) + Q_h U_h \left( \gamma_1 \left( \frac{1}{2} \right) \right) \right\}$$

$$- \int ds W_t(\gamma_1(s)) \right\}$$

is the partition function of a single lipid in external fields $W_h$, $W_t$, and $U_h$,

$$Q_c[U_c] = \int dR_c \exp [-U_c(R_c)]$$

is the partition function of a single counter ion of unit positive charge in an external...
potential $U_c$, and
\[
Q_s[W_s] = \int dR_s \exp[-W_s(R_s)]
\]  
(14)
is the partition function of a single solvent particle in the external field $W_s$. It is convenient to shift the zero of all chemical potentials so that $z_l \rightarrow 1/\nu_h$, $z_s \rightarrow z_s/\nu_h$, and $z_s \rightarrow z_s/\nu_h$. The partition function, Eq. 11, can then be written in the form
\[
Z = \int d\Phi_h dW_h d\Phi_t dW_t d\Phi_s dW_s dP_h d\Phi_t dP_t dP_c dU_c d\Xi
\]
(15)
\[
\exp\left[-\frac{\Omega}{kT}\right],
\]
with
\[
\frac{\nu_h}{kTV} \Omega = -\frac{Q_l[W_h, W_t, U_h]}{V} - z_c \frac{Q_c[U_c]}{V}
\]
(16)
\[
-\frac{Q_s[W_s]}{V} + \frac{\nu_h}{kTV} E[\Phi_h, \Phi_t, \Phi_s, P_h, P_c]
\]
\[
- \int \frac{d\mathbf{r}}{V} [W_h \Phi_h + W_t \Phi_t + W_s \Phi_s + U_h P_h + U_c P_c + \Xi(1 - \phi_h - \gamma_s \phi_s - \gamma_t \phi_t)].
\]

No approximations have been made to this point. What has been accomplished is a rewriting of the partition function from a form, Eq. 8, in which all entities interact directly with one another, to a form, Eqs. 15 and 16, in which they interact indirectly with one another via fluctuating fields. Although the integrals in Eq. 15 over $\Phi_h', \Phi_t', \Phi_s', P_h', P_c'$, and $\Xi$ could all be carried out, because they are no worse than Gaussian, the integrals over the fields $W_h', W_t', W_s', U_h', U_c$ cannot. Therefore, we use the self-consistent field theory in which we replace the integral in Eq. 15 by its integrand evaluated at its extremum. The values of $W_h', \Phi_h'$, etc., which satisfy the extremum conditions, will be denoted by the corresponding lower-case letters $w_h'$, and $\Phi_h'$, etc. The equations that determine them are six self-consistent equations for the six fields $w_h', w_t', w_s', u_h', u_c'$, and $\xi$. They are
\begin{equation}
    w_h(r) = 2\chi N \phi_h(r) + \xi(r),
\end{equation}
\begin{equation}
    w_t(r) = 2\chi N (\phi_h(r) + \phi_t(r)) + \gamma_t \xi(r),
\end{equation}
\begin{equation}
    w_s(r) = 2\chi N \phi_t(r) - \lambda (\rho_c(r) - \rho_h(r)) + \gamma_s \xi(r),
\end{equation}
\begin{equation}
    u(r) \equiv \frac{u_h(r) + u_c(r)}{2} = \frac{\beta^*}{4\pi} \int \frac{\rho_h(r') + \rho_c(r')}{R_g^2 |r - r'|},
\end{equation}
\begin{equation}
    u_s(r) \equiv \frac{u_h(r) - u_c(r)}{2} = \lambda \phi_s(r),
\end{equation}
\begin{equation}
    1 = \phi_h(r) + \gamma_t \phi_t(r) + \gamma_s \phi_s(r).
\end{equation}

Because the field $\xi$ is easily eliminated, the six equations readily reduce to five. The simplicity of Eq. 21 reduces this, in practice, to a set of four equations. The five densities $\phi_h$, $\phi_t$, $\phi_s$, $\rho_h$, and $\rho_c$ are functionals of all of the above fields except $\xi$, and, therefore, close the cycle of self-consistent equations:
\begin{equation}
    \phi_h(r)[w_h, w_t, w_h] = -\frac{\delta Q_h[w_h, w_t, w_h]}{\delta w_h(r)},
\end{equation}
\begin{equation}
    \phi_t(r)[w_h, w_t, w_h] = -\frac{\delta Q_t[w_h, w_t, w_h]}{\delta w_t(r)},
\end{equation}
\begin{equation}
    \phi_s(r)[w_s] = -z_s \frac{\delta Q_s[w_s]}{\delta w_s(r)}
\end{equation}
\begin{equation}
    = z_s \exp[-w_s(r)],
\end{equation}
\begin{equation}
    \rho_h(r)[w_h, w_t, w_h] = -\frac{\delta Q_h[w_h, w_t, w_h]}{\delta u_h(r)}
\end{equation}
The density $\Phi_h(\mathbf{r})$ is simply the expectation value of $\widehat{\Phi}_h(\mathbf{r})$ in the single lipid ensemble.

Similar interpretations follow for the other densities. Note that one of the self-consistent equations, Eq. 20, is simply the nonlinear Poisson-Boltzmann equation, and $u(\mathbf{r})$ the electric potential.

With the aid of the above equations, the mean-field free energy, $\Omega_{mf}$, which is the free energy function of Eq. 16 evaluated at the mean-field values of the densities and fields, can be put in the form

$$-\Omega_{mf} = \frac{kT}{v_h} (\mathcal{Q}_{l}[w_h, w_t, u_h] + z_c \mathcal{Q}_c[u_c] + z_s \mathcal{Q}_s[w_s])$$

$$+ E[\phi_h, \phi_t, \phi_s, \rho_h, \rho_c],$$

$$= kT(n_l + n_c + n_s) + E[\phi_h, \phi_t, \phi_s, \rho_h, \rho_c]$$

with $E$ given by Eq. 6. The thermodynamic potential, $\Omega$, is that appropriate to an incompressible system calculated in the grand ensemble; the negative of the osmotic pressure multiplied by the volume. Thus, the above equation states that the osmotic pressure is the sum of the ideal partial osmotic pressures plus a correction due to the interactions. Within mean field theory, this correction is simply the energy per unit volume of the system.

We now specify that the charges in the system can associate with or disassociate from the headgroup in response to the local electrostatic potential. This implies that the partition function of a single lipid, $\mathcal{Q}_l$ is to be averaged over the nominal charge distribution that $Q_h = 1$ with probability $p$, and $Q_h = 0$ with probability $1 - p$ (Borukhov et al., 1998[1]). The consequence of this averaging is that $\mathcal{Q}_{l}[w_h, w_t, u_h]$ of Eq. 12 becomes

$$\mathcal{Q}_l[w_{h,\text{eff}}, w_t] = \int \mathcal{D}r_1 \exp \left\{ -w_{h,\text{eff}} \left( r_1 \left( \frac{1}{2} \right) \right) - \int_0^1 ds w_t(r_1(s)) \right\},$$

where
\[ w_{h,\text{eff}}(r) \equiv w_h(r) - \ln \int dQ_h \exp[Q_h u_h(r)] \tag{33} \]

\[ = w_h(r) - \ln[1 + p(\exp[u_h(r)] - 1)]. \tag{34} \]

Although this appears to introduce an unknown parameter \( p \) into the problem, the condition of charge neutrality,

\[ \int dr \left[ \rho_h(r) + \rho_c(r) \right] = 0, \tag{35} \]

relates this parameter to the fugacity of the counter ions, \( z_c \). In practice, we use this fugacity to control the pH and the amount of charge on the lipids.

There remains only to specify how the single-lipid partition function is obtained. One defines the end-segment distribution function

\[ q(r, s) = \int D r_l(s) \delta(r - r_l(s)) \tag{36} \]

\[ \exp \left\{ - \int_0^s \! dt \left[ \frac{1}{8R_g^2} \left| \frac{dr(t)}{dt} \right|^2 \right] \right. \]

\[ + w_{h,\text{eff}}(r_l(t)) \delta \left( t - \frac{1}{2} \right) + w_l(r_l(t)) \right\}, \]

which satisfies the equation

\[ \frac{\partial q(r, s)}{\partial s} = 2R_g^2 \nabla^2 q(r, s) \tag{37} \]

\[ - \left[ w_{h,\text{eff}}(r) \delta \left( s - \frac{1}{2} \right) + w_l(r) \right] q(r, s), \]

with initial condition

\[ q(r, 0) = 1. \tag{38} \]

The partition function of the lipid is then

\[ Q_1 = \int dr \ q(r, 1). \tag{39} \]

From this expression for the single-lipid partition function and Eqs. 23, 24, and 27, one
obtains expressions for the local density of the lipid heads,

$$\phi_h(r) = \exp[-w_{h,\text{eff}}(r)] q\left(r, \frac{1}{2}\right) q\left(r, \frac{1}{2}\right),$$

(40)

of the lipid tails,

$$\phi_t(r) = \int_0^1 dq q(r, 1-s),$$

(41)

and of the charge density on the lipid heads,

$$\rho_h(r) = -\frac{p \exp[u_h(r)]}{1 + p[\exp[u_h(r)] - 1]} \phi_h(r).$$

(42)

To summarize: there are four self-consistent equations to be solved for the fields $w_h$, $w_t$, $w_s$, and electrostatic potential $u$. These equations, obtained from simple algebraic manipulation of Eqs. 17-22, can be taken to be

$$\gamma_t w_h(r) - w_t(r) = 2\chi N[\gamma_t \phi_t(r) - \phi_h(r) - \phi_s(r)],$$

(43)

$$\gamma_s w_h(r) - w_s(r) = 2\chi N(\gamma_s - 1)\phi_t(r) + \lambda(\rho_c(r) - \rho_h(r)),$$

(44)

$$1 = \phi_h(r) + \gamma_t \phi_t(r) + \gamma_s \phi_s(r),$$

(45)

$$R_g^2 \nabla^2 u(r) = -\beta^*(\rho_h(r) + \rho_c(r)).$$

(46)

Note that we have chosen here to write the Poisson-Boltzmann equation, Eq. 20, in its local, rather than its integral form. When the four fields are known, the corresponding densities follow from Eqs. 26, 29, 40, 41, and 42.

Rather than attempt to solve these equations in real space, a difficult task for the periodic phases in which we are interested, such as $H_{II}$, we recast the equations in a form that makes straightforward their solution for a phase of arbitrary space-group symmetry (Matsen and Schick, 1994[8]).

**Fourier space**

We note that the fields, densities, and the end point distribution function depend only on one coordinate $r$. Therefore, in an ordered phase, these functions reflect the space-group symmetry of that phase. To make this symmetry manifest in the solution, we expand all functions of position in a complete, orthonormal set of functions, $f_i(r)$, $i = 1, 2, 3, \ldots$, each of
which have the desired space group symmetry; e.g.,
\[ \phi_h(r) = \sum_i \phi_{h,i} f_i(r), \]  
\[ (47) \]
\[ \delta_{i,j} = \frac{1}{V} \int dr \, f_i(r) f_j(r). \]  
\[ (48) \]
Furthermore, we choose the \( f_i(r) \) to be eigenfunctions of the Laplacian
\[ \nabla^2 f_i(r) = -\frac{\lambda_i}{D^2} f_i(r), \]  
\[ (49) \]
where \( D \) is a length scale for the phase. The functions for the lamellar phase are clear. They can be taken to be
\[ f_1(r) = 1, \]  
\[ (50) \]
\[ f_i(r) = \sqrt{2} \cos[2\pi(i-1)x/D] \quad i \geq 2. \]  
\[ (51) \]
Expressions for the unnormalized basis functions for other space-group symmetries can be found in X-ray tables (Henry and Lonsdale, 1969) because they are intimately related to the Bragg peaks. In the tables cited, those for the hexagonal phase, space group (p6m) can be found on page 372, and that of the bcc phase, space group (Im3m) on page 524.

The four self-consistent equations become
\[ \gamma_t w_{h,i} - w_{t,i} = 2\chi N[\gamma_t \phi_{t;i} - \phi_{h;i} - \phi_{s;i}], \]  
\[ (52) \]
\[ \gamma_s w_{h;i} - w_{s;i} = 2\chi N(\gamma_s - 1)\phi_{t;i} + \lambda(\rho_{c;i} - \rho_{h;i}), \]  
\[ (53) \]
\[ \delta_{1,i} = \phi_{h;i} + \gamma_t \phi_{t;i} + \gamma_s \phi_{s;i}, \]  
\[ (54) \]
\[ \frac{\lambda_i D^2}{D^2} u_i = \beta^*(\rho_{h;i} + \rho_{c;i}). \]  
\[ (55) \]
To obtain the partition functions and densities, we proceed as follows. For any function \( G(r) \), we can define a symmetric matrix,
\[ (G)_{ij} = \frac{1}{V} \int f_i(r) G(r) f_j(r) \, dr. \]  
\[ (56) \]
Note that \((G)_{ii} = (G)_{i1} = G_i\), the coefficient of \(f_i(r)\) in the expansion of \(G(r)\). Matrices corresponding to functions of \(G(r)\), such as

\[
(e^G)_{ij} \equiv \frac{1}{V} \int f_i(r) e^{G(r)} f_j(r) \, dr,
\]

are evaluated by making an orthogonal transformation, which diagonalizes \((G)_{ij}\). With this definition, Eqs. 26 and 29 yield the solvent density and counter ion charge density,

\[
\phi_{si} = z_s(e^{-w_s})_{i,1},
\]

\[
\rho_{ci} = z_c(e^{-u_c})_{i,1}
\]

\[
= z_c(e^{-(u-u_0)})_{i,1}.
\]

To obtain the remaining densities, we need the end-point distribution function. From Eq. 37, we obtain

\[
\frac{dq_i(s)}{ds} = -\sum_j [A_{ij} + (w_{h,eff})_{ij}\delta(s - 1/2)]q_j(s),
\]

\[
A_{ij} = \frac{2R^2}{D^2} \lambda_i \delta_{ij} + (w_l)_{ij},
\]

with initial condition \(q_i(0) = \delta_{i,1}\). The solution of this equation is

\[
q_i(s) = (e^{-As})_{i,1} \quad \text{if } s < \frac{1}{2},
\]

\[
= \sum_j (e^{-w_{h,eff}})_{ij}(e^{-A/2})_{j,1} \quad s = \frac{1}{2},
\]

\[
= \sum_{j,k} (e^{-A(s-1/2)})_{ij}(e^{-w_{h,eff}})_{jk}(e^{-A/2})_{k,1} \quad s > \frac{1}{2}.
\]

From this, the remaining densities follow from Eqs. 40, 41, and 42:

\[
\phi_{hi} = \sum_{jkl} (e^{-w_{h,eff}})_{ij} \Gamma_{jkl} q_k(\frac{1}{2}-)q_l(\frac{1}{2}-),
\]

\[
\rho_c = \sum_{ijkl} (e^{-w_{h,eff}})_{ij} \Gamma_{jkl} q_k(\frac{1}{2}-)q_l(\frac{1}{2}-).
\]
\[
\phi_{t;i} = \frac{1}{0} \int ds \sum_{jk} \Gamma_{ijk} q_j(s) q_k(1 - s), \tag{65}
\]

\[
\rho_{h;i} = -\sum_j \left( \frac{p e^{u_h}}{1 + p(e^{u_h} - 1)} \right) \phi_{h;j}, \tag{66}
\]

with

\[
\Gamma_{ijk} = \frac{1}{V} \int f_i(r) f_j(r) f_k(r) dr. \tag{67}
\]

The mean-field free energy, Eq. 31, takes the form

\[
-\Omega_{mf} = \frac{kTV}{v_h} (\phi_{t;1} + \phi_{s;1} + \rho_{c;1}) + E, \tag{68}
\]

with the mean-field energy being given by

\[
E = \frac{kTV}{v_h} \sum_i [2\chi N(\phi_{h;i} + \phi_{s;i}) \phi_{t;i} + \frac{1}{2}(\rho_{h;i} + \rho_{c;i}) u_i - \lambda(\rho_{c;i} - \rho_{h;i}) \phi_{s;i}]. \tag{69}
\]

We have expressed the Coulomb energy as a product of the charge densities and electrostatic potential. Note that this free energy still depends parametrically on \( D \), the length scale of the phase, so that the value of \( D \) that minimizes it must be determined. Once this is done, we compare the free energies obtained for phases of different space-group symmetry, and thereby determine the phase diagram of our model lipid system.

The infinite set of self-consistent equations, Eqs. 52-55 must be truncated to be solved numerically. We have used up to 50 basis functions. This truncation is sufficient to ensure, for \( T^* > 0.03 \) and \( 1/(1 + \gamma) < 0.66 \), an accuracy of \( 10^{-4} \) in the free energy \( v_h \Omega_{mi}/kTV \). As noted, one must also determine the length scale that minimizes the free energy. This is usually straightforward because there is a single well-defined minimum for a phase of given symmetry at given thermodynamic parameters: temperature, and chemical potentials. Were there more than one minimum, this would reflect a tendency for the system to phase separate into two phases with the same nontrivial space-group symmetry, an extremely unusual occurrence. The single minimum that one finds normally is sharp, that is, the free energy varies rather rapidly with \( D \). Only in cases in which phases are greatly swollen is the minimum extremely shallow and difficult to locate.
RESULTS

The neutral lipid

We first apply our method to a neutral lipid. We show here the phase behavior of the neutral lipid, in the absence and in the presence of solvent. Figure 1 shows the phase diagram of the pure lipid as a function of the dimensionless temperature $T^*$, and the architecture of the lipid. The latter is characterized by the single parameter $1/(1 + \gamma_t)$ which is the relative volume of the headgroup to that of the entire lipid. It is analogous to, but not the same as, the single parameter used by Israelachvili (1985) to characterize the geometry of lipids. Shown are the lamellar phase, $L_\alpha$, the normal and inverted hexagonal phases, $H_1$ and $H_{II}$, and the normal and inverted body-centered cubic phases $bcc_1$ and $bcc_{II}$. The occurrence of bicontinuous phases will be discussed in a later paper.

One sees that the phase behavior is reasonable and in accord with packing considerations; as the headgroup increases in volume, the system passes through a series of phases from the inverted ones with most curvature, through the lamellar phase, to the normal ones of most curvature. To model a lipid, which, like phosphatidylserine, adopts the $H_{II}$ configuration when essentially neutral (Cullis et al., 1985, Bezrukov et al., 1998), we have chosen $1/(1 + \gamma_t) = 0.24$ in our subsequent studies. For comparison, the value appropriate for DOPE, calculated from the molecular volumes in the literature (Rand and Fuller, 1994), is 0.254. For the convenience of the reader interested in carrying out similar calculations, we

**FIGURE 1** Phase diagram of the neutral lipid as a function of dimensionless temperature, $T^* \equiv 1/2 \sqrt{\chi N}$, and relative headgroup volume, $1/(1 + \gamma_t)$. In addition to the disordered phase, $D$, there are normal and inverted body-centered cubic phases, $bcc_1$ and $bcc_{II}$, normal and inverted hexagonal phases, $H_1$ and $H_{II}$, and the lamellar phase $L_\alpha$.

present, in Table 1, the values of the first three nontrivial Fourier components of the headgroup density $\Phi_h(r)$, the lattice parameter $D/R_g$, and the free energy $\Omega_{mf} v_h/kTV$ for the $L_\alpha'$, $H_{II}$, and $bcc_{II}$ phases at $T^* = 0.04$. We note, in passing, that the relative intensities of X-ray Bragg peaks can be determined directly from the Fourier components of the various densities with which they are associated.

| TABLE 1 Anhydrous, neutral lipid: the lattice parameter, the free energy, and the first three non-trivial Fourier components of $\Phi_h(r)$ for $L_\alpha'$, $H_{II}$, and $bcc_{II}$ phases at $T^* = 0.04$ and $1/(1 + \gamma_t) = 0.24$

The effect on this neutral lipid of the addition of a solvent of small volume, characterized by $\gamma_s = v_s/v_h = 0.1$, close to the value of 0.096 (Rand and Fuller, 1994; Kozlov et al., 1994), appropriate to water and a phosphatidylethanolamine headgroup, is shown in Fig. 2. There is a lamellar phase at small solvent volume fractions and low temperatures. This phase becomes unstable with respect to the $H_{II}$ phase, which envelops it at higher temperatures.

There is a large region of two-phase coexistence between the ordered lipid-rich phases and an almost pure solvent phase. These features are reasonable, and are observed in the systems of aqueous dialkyl didodecylphosphatidylethanolamine and of diacyl diarachinoylphosphatidylethanolamine (Seddon et al., 1984). Of particular interest is that we find a small temperature region of re-entrant hexagonal-lamellar-hexagonal transitions, an unusual feature that has been observed in DOPE (Gawrisch et al. 1992; Kozlov et al. 1994). As a consequence, there is an azeotrope at which the transition between lamellar and hexagonal phases occurs without a change in the concentration of water. We have used the coordinates of this point, $T^* = 0.06$ and $\Phi_s = 1.42$, denoted $T_0$ and $(\Phi_s')_0$ to normalize the temperature and solvent-density axes. There is a small region of $bcc_{II}$ in our phase diagram.

Again, the possible occurrence of bicontinuous phases will be examined in a later publication. The uncertainty in the temperature of the phase boundaries, $\delta T/T$ introduced by the truncation of the number of basis functions, is approximately $2 \times 10^{-3}$. 
As the volume fraction of water is increased, we find that the period of all structures increases, as is expected. In Fig. 3, we compare experimental results on DOPE taken in the inverted hexagonal phase at a temperature $T = 22^\circ$C, just above that of the azeotrope (Rand and Fuller, 1994), to our values calculated just above the azeotrope. Knowing the molecular weight of DOPE, we convert the volume fraction of solvent, $\gamma_s \phi_s$, which occurs in the calculation, to the experimental variable of weight fraction of water. The lattice parameter of the hexagonal phase in the calculation, however, is measured in units of the radius of gyration of either lipid tail. What value should be taken to model DOPE is unknown. Hence, we have used, in the comparison, the lattice parameter $D$, in units of $D_0$, the lattice parameter at the azeotrope. The agreement is excellent.
An effective value of the radius of gyration can be defined as that value that brings agreement between the calculated and measured lattice parameters. As the former, at the azeotrope, is \( D(T_0) \equiv D_0 = 4.79 R_g^0 \), and the latter is 58.9 Å (Rand and Fuller, 1994), the equivalent radius of gyration at the temperature of the azeotrope, \( R_g^0 \), is 12.3 Å for a single tail, not unreasonable when compared to the extended length of a single chain of DOPE, which is approximately 26 Å.

As the temperature of the system is lowered, the period of all structures increases, which is due to the lengthening of the tails as their entropy decreases. We would again like to compare our results with those of the DOPE system. To do so, we must address the temperature dependence of the radius of gyration, \( R_g \), which appears in the theory, and which is not given a priori. Because the model chain is flexible, the radius of gyration is related to the mean square end-to-end distance, \( \bar{R} \), by a numerical constant, \( R_g = \bar{R}/\sqrt{6} \), so their dependence on temperature is the same. To compare our results to DOPE, we shall assume that the temperature dependence of the radius of gyration that appears in the calculation is the same as that given for lipid chains by the Rotational Isomeric States Model, a model that describes the properties of such chains very well (Flory, 1969; Mattice and Suter, 1994). Thus we assume

\[
R_g(T) = c \left( \frac{1 - \langle \cos \phi \rangle}{1 + \langle \cos \phi \rangle} \right)^{1/2},
\]

where the angle \( \phi \) takes the values 180° and ±70° corresponding to trans, gauche+ and gauche− configurations, and \( c \) is a constant. The statistical average of \( \cos \phi \) is

\[
\langle \cos \phi \rangle = \frac{\cos(180^\circ) + \sigma \cos(70^\circ) + \sigma \cos(-70^\circ)}{1 + 2\sigma},
\]

with \( \sigma = \exp(-T_{\text{rism}}/T) \) and \( T_{\text{rism}} = 280.25 \, \text{K} \). From the behavior with temperature of \( R_g(T) \), the lattice parameter, \( D(T) \), at any temperature can be obtained from

\[
\frac{D(T)}{D(T_0)} = \left[ \frac{D(T)/R_g(T)}{D(T_0)/R_g(T_0)} \right] \frac{R_g(T)}{R_g(T_0)}.
\]

Again, it is the factor \( D(T)/R_g(T) \) that occurs naturally in the calculation.

A comparison of the experimentally measured (Kirk and Gruner, 1985; Tate and Gruner, 1989) and theoretically calculated lattice parameters versus temperature is shown in Fig. 4. In part (a), the variation of the parameter of the \( H_{\|} \) is shown at two different lipid weight
fractions. The agreement is very good. In part (b), the comparison is made of the $H_{II}$ and $L_\alpha$ parameters along the coexistence with excess water. Note that this comparison is a much more stringent test, because it requires not only that the dependence of the lattice parameters on solvent concentration and on temperature be reproduced well by the calculation, but also that the phase boundaries be given well. Considering these requirements, the agreement is rather good. It should be noted that the agreement in Fig. 4 b does not depend on the exact temperature of the triple point, which is difficult to locate precisely, but only on the existence of stable $H_{II}$ and $L_\alpha$ phases, which coexist with excess water.

**FIGURE 4** Comparison of theoretically calculated and experimentally measured values of the lattice parameter, $D(T)/D_0$, versus absolute temperature $T$ (a) for two different weight fractions of lipid, $\Phi^w_1$, and (b) along coexistence with excess water. The absolute temperature of the azeotrope is denoted $T_0$.

As seen in Fig. 4 b, the lattice parameter of the $H_{II}$ phase is much larger than that of the $L_\alpha$ at the triple point. This is due to the coexistence with excess solvent, which swells the hexagonal cores, but which is only weakly present between the lamellae. In contrast, when the lamellar and hexagonal phases are only in two-phase coexistence with one another and there is no excess solvent, the hexagonal phase, in general, has a smaller lattice parameter than the coexisting lamellar phase, as shown in Fig. 5. This is because, over almost all of their coexistence region, the $H_{II}$ phase has a smaller volume fraction of solvent than does the $L_\alpha$ phase, as can be seen from the phase diagram of Fig. 2. Only over the re-entrant region, which occurs as the triple point is approached, does this balance shift. This shift in the relative size of the latter parameters through the re-entrant region is in agreement with experiment (Kozlov et al., 1994).
It is of interest to determine if any one effect can be said to drive the transition from the $H_{\|}$ to $L_\alpha$ phase in the neutral system. To this end, we examine the individual terms in the thermodynamic potentials per unit volume $\Omega_{mf} = Ev_h/kTV - S_v h/kV - (S_v h/kV + \phi s \ln z_s)$ of the $L_\alpha$ and $H_{\|}$ phases, as the transition is crossed, by increasing the solvent fugacity, $z_s$, at constant temperature $T/T_0 = 0.67$. In Table 2, we show the contributions to the free energy per unit volume of the $L_\alpha$ phase and that of the $H_{\|}$ phase coming from the interaction energy, $Ev_h/kTV$, the lipid tails, $-S_v h/kV$, and the solvent $-S_v h/kV - \phi s \ln z_s$. All contributions are evaluated at the transition itself, which occurs at $z_s \approx 3.15$, and are measured with respect to the free energy per unit volume of the disordered phase. We also show the difference in the contribution of each term to the free energies of each phase, and the derivative of this difference with respect to the solvent fugacity. The difference in the contribution of the entropy of the lipid tails is positive because, with the lipid architecture we have chosen, the large tail volume relative to that of the head favors the hexagonal phase. The interaction energy favors the lamellar phase, as does the solvent, presumably because the interstices of that phase are two-dimensional, whereas those of the inverted hexagonal phase are one-dimensional. The difference between the lipid entropy contributions decreases with increasing solvent concentration because the packing constraints in the $H_{\|}$ phase become more severe as the size of the cores increases (Gruner, 1989). However, it is apparent that neither this term, nor either of the others, changes so rapidly with solvent concentration compared to the others that any particular effect can be said to drive this transition.
The charged lipid

We now turn on the negative charge of the headgroups by varying the chemical potential of the free counter ions while enforcing charge neutrality. Increasing the density of free, positive counter ions in our closed system is equivalent to increasing the magnitude of the negative charge density on the headgroups. It therefore corresponds to an increase in the pH of an experimental system. The charge on the headgroups is annealed, meaning that it is determined by the local value of the electrostatic potential, and therefore the headgroup charge varies with the location of that group. The parameter $\beta^*$, defined in Eq. 7, measures the strength of the Coulomb interaction. It can be written as the ratio of two lengths, $\beta^* = \xi/L_1$, where $\xi \equiv e^2/\varepsilon kT$ is the Bjerrum length, and $L_1 \equiv v_h/4\pi R_G^2$ is a length characterizing the architecture of the lipid. It is reasonable that $\beta^*$ be larger than, or of order, unity, and we have arbitrarily taken $\beta^* = 1$.

In addition to the Coulomb interaction, the short-ranged, thermally averaged interaction between charges and the water dipole is also of importance. It varies with separation $r$ as $(kT/6)(ue^2)(\xi^2/r)^4 \equiv \omega(r)$, with $u$ the dipole moment of water and $\xi$, the Bjerrum length. The above expression is valid for distances such that $r/\xi > (ue\xi)^{1/2}$. For water, $\xi \approx 7$ Å, and $\omega(r)/kT \approx 4.6 \times 10^{-4}(\xi/r)^4$. To approximate this short-ranged interaction by a contact interaction of dimensionless strength, $\lambda$, it is equivalent to using $\omega/kT$ evaluated at some fixed distance. Any reasonable choice shows that $\lambda$ is small. We have arbitrarily chosen $\lambda = 0.1$, which corresponds to $\omega(r)/kT$ evaluated at 1.9 Å, a distance within the regime in which the approximate expression for the charge-dipole interaction is valid.

Shown in Fig. 6 is the temperature of the transition, $T^*$, between $H_{\Pi}$ and $L_\alpha$ phases as a function of the magnitude of the average charge density on the headgroups, $\bar{\rho}_h \equiv \rho_{h,1}$. The range of charge density corresponds to the headgroups varying from being neutral to fully charged. The region beyond the almost vertical line at $|\bar{\rho}_h| \approx 0.22$ would correspond to the headgroups being charged with a probability greater than unity, and is therefore unphysical. The maximum value of $|\bar{\rho}_h|$ is slightly different in the two phases. One sees that, with increasing headgroup charge equivalent to increasing pH, the inverted hexagonal phase becomes unstable with respect to the lamellar phase, just as in the experiments on phosphatidylserine in water (Hope and Cullis, 1980; Bezrukov et al., 1998). Furthermore,
the pH at the transition increases with increasing temperature, in accord with experiment (Hope and Cullis, 1980).

**FIGURE 6** Transition temperature between $L_\alpha$ and $H_{\Pi}$ phases for the same lipid as in Fig. 2, but now with a charged headgroup. The dimensionless strength of the Coulomb interaction is $\beta^* = 1$, and that of the interaction between charges and neutral solvent is $\lambda = 0.1$. The solvent fugacity is fixed at $z_s = 3$.

In Fig. 7a, we show the volume fraction profiles in the $L_\alpha$ phase at a value of $z_c = 0.1228$, $z_s = 3$, and temperature $T^* = 0.04$ at which the $H_{\Pi} - L_\alpha$ transition occurs. The position through the system is divided by the lattice parameter of the phase, which, in units of the radius of gyration of the lipid, is $D_L/R_g \approx 4.14$. All looks reasonable. In particular, the volume fraction of solvent within the bilayer is negligible, in agreement with molecular dynamic simulations of a single charged bilayer (López Cascales et al., 1996). We obtain similar results when the lipid is neutral. In Fig. 7b, the charge density profile of the same structure is shown. One sees that the charge on the headgroup mimics, but does not reproduce, the headgroup volume fraction. This is because the charge on the headgroup is not fixed, but varies with the local electrostatic potential. The counter ion density is fairly uniform because we have used a single dielectric constant, that of water, throughout the system. In principle, a more realistic position-dependent dielectric constant could be used, which would lead to a reduced counter ion density in the tail region. Such a procedure would entail a significant change in the Poisson-Boltzmann equation, Eq. 46, because it is the divergence of the electric displacement.

$$-\nabla \cdot [\varepsilon(r)\nabla u(r)] = -\varepsilon(r)\nabla^2 u(r) - \nabla u(r) \cdot \nabla \varepsilon(r),$$

that is proportional to the free charge density. The second term cannot be ignored in the region around the headgroups where the dielectric constant varies rapidly between its values in the tail and water regions. It accounts for the orientation of water dipoles near the
headgroups. The fact that the position-dependent dielectric constant depends on the initially unknown head, tail, and solvent densities, \( \varepsilon(\mathbf{r}) = \varepsilon_h \Phi_h(\mathbf{r}) + \varepsilon_t \Phi_t(\mathbf{r}) + \varepsilon_s \Phi_s(\mathbf{r}) \), further complicates the equation. For these reasons, we have used the uniform dielectric constant in this initial study. Interestingly, the approximation of a uniform dielectric would have much less effect had we modeled larger counter ions, such as Na\(^+\). Their very size, coupled with the incompressibility conditions and the interactions, would cause their density in the tail region to be much reduced (López Cascales et al., 1996) when calculated by the Poisson-Boltzmann equation (Borukhov et al., 1997).

**FIGURE 7** (a) Volume fraction distribution in the \( L_\alpha \) phase of the solvent, headgroups, and tails, in the system of Fig. 6 at a counter ion chemical potential of \( z_c = 0.1228 \) corresponding to the \( L_\alpha \rightarrow H_{II} \) transition. The temperature is \( T^* = 0.04 \), and the lattice parameter of the lamellar phase is \( D_L/R_g = 4.14 \). (b) Charge densities arising from the headgroups, the counter ions, and the total charge density in the \( L_\alpha \) phase under the same conditions as in (a).

In Fig. 8, we show the volume fraction and charge density profiles for the \( H_{II} \) phase at the same value of \( z_c \) as in Fig. 7. The cut through the system is taken along the nearest-neighbor direction, and the distance is normalized to its lattice parameter \( D_{H} \approx 3.83R_g \). Again, the wavelength of the \( H_{II} \) phase is smaller than that of the \( L_\alpha \) phase because, in two-phase coexistence, i.e., in the absence of a reservoir of excess water, the cores of the cylinders are not swollen with water, and the hexagonal phase contains a smaller volume fraction of water than does the lamellar phase. One can infer from Fig. 8a that, in the nearest-neighbor direction, there is far more interdigitation of lipid tails than in the lamellar phase. This makes sense, because the tails must certainly stretch to fill the space between cores in the second-neighbor direction, so that interdigitation is expected in the nearest-neighbor direction.
To investigate this transition further, we show, in Table 3, the contributions in the $L_\alpha$ and the $H_{II}$ phases of the various terms in the thermodynamic potential per unit volume $\Omega$

$$
\Omega_{v_h}/kTV = (E_1 + E_2 + E_3)v_h/kTV - S_1 v_h/kV - (S_s v_h/kV + \phi_s \ln z_s) - (S_c v_h/kV + \rho_c \ln z_c).
$$

Here $E_1$ is the hydrophilic-hydrophobic interaction proportional to $\chi_N$, $E_2$ is the electrostatic interaction proportional to $\beta_s$, and $E_3$ is the charge-solvent interaction proportional to $\lambda$.

These contributions are evaluated at the transition itself, and are measured from the free energy per unit volume of the disordered phase. We also show the difference between these contributions to each phase, and the derivatives of each of these differences with respect to the counter ion fugacity, $z_c$. There are several interesting things to note. The electrostatic energy is a relatively small contribution to the free energy of each phase, and hardly differs between them. Therefore, it does not have a large effect in bringing about the transition. The contribution of the counter ions to the free energy of each phase is of the same order of magnitude as the electrostatic interaction and, like it, does not change rapidly with the counter ion fugacity. The contribution of the short-range charge-solvent interaction is small, but it changes most rapidly with the counter ion fugacity, and, therefore, appears to be most important in actually bringing about the transition itself.
The physical mechanism in the experimental system appears to be clear. The lipid with an almost neutral headgroup forms the $H_{\text{II}}$ phase because the volume of the headgroup is relatively small compared to that of the entire lipid. As the charge on the headgroup is turned on, it attracts an increasing volume of waters of hydration via the attractive interaction between the charge and the dipoles of water. In addition, more counter ions, enlarged by their own waters of hydration, are attracted to the headgroup. Thus, the headgroup becomes effectively larger, and drives the transition to the $L_{\alpha}$ phase.

Just as we have calculated the variation with temperature and solvent concentration of the $H_{\text{II}}$ lattice constant of neutral DOPE, so we should be able to calculate its recently measured variation with salt concentration in binary mixtures of DOPE and dioleoylphosphatidic acid, (Döbereiner, unpublished). It would be interesting to do so.
