## Nondestructive Characterization of Silicon-on-Insulator Wafers

Silicon-on-insulator (SOI) is a preferred technology for leading edge, small devices in future integrated circuits. However, one of the challenges is the measurement of the thin silicon layers that make up the active portions of the circuit. Such measurements should be simple and be nondestructive so that wafers can be measured upon receipt. Arizona State University, a participant in SiWEDS Center research, has developed in conjunction with Four Dimensions, Inc., the manufacturer of the mercury probe, a technique using this probe to serve as source and drain of the MOSFET. Measurement of the thin silicon layers are now simple and non-destructive so wafers can be measured upon receipt. The device allows the current to be measured from which one extracts the carrier mobility, a very important device parameter, the threshold voltage, defect information, and the doping concentration. The technique is used by some of the SOI wafer producers, e.g., Gritek, MEMC, Komatsu, and LG Siltron. For more information, contact Dieter K. Schroder, Arizona State University, 480-965-6621; e-mail: schroder@asu.edu.

## Comprehensive model of properties of copper in silicon

The copper interconnect technology has become the mainstream technology for the manufacturing of high performance chips. This requires development of procedures and tools for contamination control of copper in silicon wafers and for removal of Cu from reclaim wafers. University of California at Berkeley, a participant of the SiWEDS Center, studies diffusion, electrical properties, and gettering of copper in bulk silicon. In the framework of this research, several breakthroughs were achieved in the area of understanding the fundamental physical properties of copper in silicon and which resulted in classical textbook data on Cu in Si to be revised. It was demonstrated that the diffusion barrier for copper is silicon is not 0.43 eV, as it was thought for nearly forty years, but only 0.18 eV. Correspondingly, the diffusivity of Cu at room temperature is about three orders of magnitude higher than it was thought. This allows copper to diffuse substantial distances in silicon at room temperature and explains the kinetics of the phenomena of Cu contamination during chemomechanical polishing and of its outdiffusion to the surface during storage at room temperature. This data was provided to the SiWEDS member companies, which used it for improving of their technological processes. The ongoing collaborative effort between Intel and several wafer suppliers to develop a standard metrology of Cu contamination control relies to a large extent on this data. ## Process of Interfaceless Oxynitride Thin Layer

Dr. A. Karoui and Prof. Rozgonyi's team at the NC State University have developed methods for growing shallow oxynitride layers with unique properties on silicon wafers. The starting material is nitrogen doped commercial Czochralski Si, with an initial nitrogen level of about 1E15cm$^{-3}$, lower levels can be used for growing shallower layers. The strong N segregation enriches the subsurface zone, which results in oxygen gettering. Unlike deposited oxynitride layers, the new layers are grown from the bulk with a smooth N and O concentration gradients. At a few microns away (or less) from the surface, N and O concentrations are increasing and peaking at the surface. The layers grown with this method are crystalline, continuous and interfaceless thus do not have interface states, known to be harmful for charge carriers. In addition, no charge center exists in these crystalline oxynitride unlike the amorphous ones grown by chemical vapor deposition. Knowing that interface states and charged centers found in add on oxynitride layers can be detrimental for devices, the new oxynitride layer are of interest for IC technology. Depending on the layer thickness and the [N] to [O] ratio, three novel processes are used:

1) Fine sliced N doped Si wafers are grinded to generate submicrometer roughness while exerting mechanical stress on the surface, then finely polished by chemical and mechanical polishing process (CMP). The thickness of the layer is in the nanoscale range, up to 0.5 microns. The nitrogen concentration reaches eight times and oxygen twice their respective solubility limits.

2) Anneal N doped wafers at 650°C for 8 hours, then at 1050°C for 10 hours. This process results in N and O concentrations up to 1E18 cm$^{-3}$ and 2E20 cm$^{-3}$, respectively. The maximum breadth of this layer is 1.5 microns.

3) Anneal at 650°C for 16 hours, NCZ silicon wafer. For N doping level of 5E14 cm$^{-3}$, this process gives the maximum layer breadth, about 2 microns. For more information, contact Abdennaceur Karoui, NCSU, 919-515-7217; e-mail: nas_karoui@ncsu.edu.
