17.4	Outlook	24
17.5	Acknowledgments	24

Many physical processes considered in the Review of Particle Properties (RPP) involve hadrons. The properties of hadrons—which are composed of quarks and gluons—are governed primarily by Quantum Chromodynamics (QCD) (with small corrections from Quantum Electrodynamics [QED]). Theoretical calculations of these properties require non-perturbative methods, and Lattice Quantum Chromodynamics (LQCD) is a tool to carry out such calculations. It has been successfully applied to many properties of hadrons. Most important for the RPP are the calculation of electroweak decay constants and form factors, which are needed to extract Cabibbo-Kobayashi-Maskawa (CKM) matrix elements when combined with the corresponding experimental measurements. LQCD has also been used to determine other fundamental parameters of the standard model, in particular the strong gauge coupling and quark masses, as well as to predict hadronic contributions to the anomalous magnetic moment of the muon, $a_\mu - 2$.

This review describes the theoretical foundations of LQCD and sketches the methods used to calculate the quantities relevant for the RPP. It also describes the various sources of error that must be controlled in a LQCD calculation. Results for hadronic quantities are found in the corresponding dedicated reviews.

17.1 Lattice regularization of QCD

Gauge theories form the building blocks of the Standard Model. While the SU(2) and U(1) parts have weak couplings and can be studied accurately with perturbative methods, the SU(3) component—QCD—is only amenable to a perturbative treatment at high energies. The growth of the gauge coupling in the infrared—the flip-side of asymptotic freedom—requires the use of non-perturbative methods to determine the low energy properties of QCD. Lattice gauge theory, proposed by K. Wilson in 1974 [1], provides such a method, for it gives a non-perturbative definition of vector-like gauge field theories such as QCD. In lattice regularized QCD—commonly called lattice QCD or LQCD—Euclidean space-time is discretized, usually on a hypercubic lattice with lattice spacing a , with quark fields placed on sites and gauge fields on the links between sites. The lattice spacing plays the role of the ultraviolet regulator, rendering the quantum field theory finite. The continuum theory is recovered by taking the limit of vanishing lattice spacing, which can be reached by tuning the bare gauge coupling to zero according to the renormalization group.

Unlike dimensional regularization, which is commonly used in continuum QCD calculations, the definition of LQCD does not rely on the perturbative expansion. Indeed, LQCD allows non-perturbative calculations by numerical evaluation of the path integral that defines the theory.

Practical LQCD calculations are limited by the availability of computational resources and the efficiency of algorithms. Because of this, LQCD results come with both statistical and systematic errors, the former arising from the use of Monte-Carlo integration, the latter, for example, from the use of non-zero values of a . There are also different ways in which the QCD action can be discretized, and all must give consistent results in the continuum limit, $a \rightarrow 0$. It is the purpose of this review to provide an outline of the methods of LQCD, with particular focus on applications to particle physics, and an overview of the various sources of error. This should allow the reader to better understand the LQCD results that are presented in other reviews, primarily those on “Quark Masses,” “Quark Model,” “Quantum Chromodynamics,” “CKM quark-mixing matrix,” “ V_{ud} , V_{us} , Cabibbo angle and CKM Unitarity,” “Leptonic Decays of Charged Pseudoscalar Mesons,” “ B^0 - \bar{B}^0 Mixing,” and “Semileptonic b -Hadron Decays, Determination of V_{cb} and V_{ub} .” For more extensive explanations the reader should consult the available textbooks or lecture notes, the most up-to-date of which are Refs. [2–4].

17.1.1 Gauge invariance, gluon fields and the gluon action

A key feature of the lattice formulation of QCD is that it preserves gauge invariance. This is in contrast to perturbative calculations, where gauge fixing is an essential step. The preservation of gauge invariance leads to considerable simplifications, e.g., restricting the form of operators that can mix under renormalization.

The gauge transformations of lattice quark fields are just as in the continuum: $q(x) \rightarrow V(x)q(x)$ and $\bar{q}(x) \rightarrow \bar{q}(x)V^\dagger(x)$, with $V(x)$ an arbitrary element of SU(3). The only difference is that the Euclidean space-time positions x are restricted to lie on the sites of the lattice, i.e. $x = a(n_1, n_2, n_3, n_4)$ for a hypercubic lattice, with the n_j being integers. Quark bilinears involving different lattice points can be made gauge invariant by introducing the gluon field $U_\mu(x)$. For example, for adjacent points the bilinear is $\bar{q}(x)U_\mu(x)q(x+a\hat{\mu})$, with $\hat{\mu}$ the unit vector in the μ 'th direction. (This form is used in the construction of the lattice covariant derivative.) This is illustrated in Fig. 17.1. The gluon field (or “gauge link”) is an element of the group, SU(3), in contrast to the continuum field A_μ which takes values in the Lie algebra. The bilinear is invariant if U_μ transforms as $U_\mu(x) \rightarrow V(x)U_\mu(x)V^\dagger(x+a\hat{\mu})$. The lattice gluon field is naturally associated with the link joining x and $x+a\hat{\mu}$, and corresponds in the continuum to a Wilson line connecting these two points, $\text{P exp}(i \int_x^{x+a\hat{\mu}} dx_\mu A_\mu^{\text{cont}}(x))$ (where P indicates a path-ordered integral, and the superscript on A_μ indicates that it is a continuum field). The trace of a product of the $U_\mu(x)$

around any closed loop is easily seen to be gauge invariant and is the lattice version of a Wilson loop.

Figure 17.1: Sketch of a two-dimensional slice through the $\mu - \nu$ plane of a lattice, showing gluon fields lying on links and forming either the plaquette product appearing in the gauge action or a component of the covariant derivative connecting quark and antiquark fields.

The simplest possible gauge action, usually called the Wilson gauge action, is given by the product of gauge links around elementary plaquettes:

$$S_g = \beta \sum_{x, \mu < \nu} \left[1 - \frac{1}{3} \text{ReTr}[U_\mu(x)U_\nu(x+a\hat{\mu})U_\mu^\dagger(x+a\hat{\nu})U_\nu^\dagger(x)] \right]. \quad (17.1)$$

This is illustrated in Fig. 17.1. For small a , assuming that the fields are slowly varying, one can expand the action in powers of a using $U_\mu(x) = \exp(iaA_\mu(x))$. Keeping only the leading non-vanishing term, and replacing the sum with an integral, one finds the continuum form,

$$S_g \longrightarrow \int d^4x \frac{1}{4g_{\text{lat}}^2} \text{Tr}[F_{\mu\nu}^2(x)], \quad (17.2)$$

$$(F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + i[A_\mu, A_\nu])$$

as long as one chooses $\beta = 6/g_{\text{lat}}^2$ for the lattice coupling. In this expression, g_{lat} is the bare gauge coupling in the lattice scheme, which can be related (by combining continuum and lattice perturbation theory) to a more conventional gauge coupling such as that in the $\overline{\text{MS}}$ scheme (see Sec. 17.3.4 below).

In practice, the lattice spacing a is non-zero, leading to discretization errors. In particular, the lattice breaks Euclidean rotational invariance (which is the Euclidean version of Lorentz invariance) down to a discrete hypercubic subgroup. One wants to reduce discretization errors as much as possible. A very useful tool for understanding and then reducing discretization errors is the Symanzik effective action: the interactions of quarks and gluons with momenta low compared to the lattice cutoff ($|p| \ll 1/a$) are described by a continuum action consisting of the standard continuum terms (e.g., the gauge action given in Eq. (17.2)) augmented by higher dimensional operators suppressed by powers of a [5]. For the Wilson lattice gauge action, the leading corrections to the continuum terms come in at $\mathcal{O}(a^2)$. They take the form $\sum_j a^2 c_j \mathcal{O}_6^{(j)}$, with the sum

running over all dimension-six operators $O_6^{(j)}$ allowed by the *lattice* symmetries, and c_j unknown coefficients. Some of these operators violate Euclidean rotational invariance, and all of them lead to discretization errors of the form $a^2\Lambda^2$ (up to $\log(a)$ corrections that will be discussed below), where Λ is a typical momentum scale for the quantity being calculated. These errors can, however, be reduced by adding corresponding operators to the lattice action and tuning their coefficients to eliminate the dimension-six operators in the effective action to a given order in perturbation theory or even non-perturbatively. This is the idea of the Symanzik improvement program [5]. In the case of the gauge action, one adds Wilson loops involving six gauge links (as opposed to the four links needed for the original plaquette action, Eq. (17.1)) to define the $\mathcal{O}(a^2)$ improved (or “Symanzik”) action [6]. In practical implementations, the improvement is either at tree-level (so that residual errors are proportional to $\alpha_s a^2$, where the coupling is evaluated at a scale $\sim 1/a$), or at one-loop order (errors proportional to $\alpha_s^2 a^2$). Another popular choice is motivated by studies of renormalization group (RG) flow. It has the same terms as the $\mathcal{O}(a^2)$ improved action but with different coefficients, and is called the RG-improved or “Iwasaki” action [7].

17.1.2 Lattice fermions

Discretizing the fermion action turns out to involve subtle issues, and the range of actions being used is more extensive than for gauge fields. Recall that the continuum fermion action is $S_f = \int d^4x \bar{q}[D_\mu \gamma_\mu + m_q]q$, where $D_\mu = \partial_\mu + iA_\mu$ is the gauge-covariant derivative. The simplest discretization replaces the derivative with a symmetric difference:

$$D_\mu q(x) \longrightarrow \frac{1}{2a}[U_\mu(x)q(x + a\hat{\mu}) - U_\mu(x - a\hat{\mu})^\dagger q(x - a\hat{\mu})]. \quad (17.3)$$

The factors of U_μ ensure that $D_\mu q(x)$ transforms under gauge transformations in the same way as $q(x)$, so that the discretized version of $\bar{q}(x)\gamma_\mu D_\mu q(x)$ is gauge invariant. The choice in Eq. (17.3) leads to the so-called naive fermion action. This, however, suffers from the fermion doubling problem—in d dimensions it describes 2^d equivalent fermion fields in the continuum limit. The appearance of the extra “doubler” fermions is related to the deeper theoretical problem of formulating chirally symmetric fermions on the lattice. This is encapsulated by the Nielsen-Ninomiya theorem [8]: one cannot define lattice fermions having exact chiral symmetry of the standard form $\delta q = \epsilon \gamma_5 q$, $\delta \bar{q} = \epsilon \bar{q} \gamma_5$ (ϵ is infinitesimal) without producing doublers. Naive lattice fermions do have chiral symmetry but at the cost of introducing 15 unwanted doublers (for $d = 4$).

There are a number of different strategies for dealing with the doubling problem, each with their own theoretical and computational advantages and disadvantages. Wilson fermions [1] add a term proportional to $a\bar{q}\Delta q$ to the fermion action (the “Wilson term”—in which Δ is a covariant lattice Laplacian). This gives a mass of $\mathcal{O}(1/a)$ to the doublers, so that they decouple in the continuum limit. The Wilson term, however, violates chiral symmetry at non-zero lattice spacing, and introduces discretization errors linear in a . A commonly used variant that eliminates the $\mathcal{O}(a)$ discretization error is the $\mathcal{O}(a)$ -improved Wilson (or “clover”) action [9]. In this application of Symanzik improvement, methods have been developed to remove $\mathcal{O}(a)$ terms non-perturbatively using auxiliary simulations to tune parameters [10]. Such “non-perturbative improvement” is of great practical importance as it brings the discretization error from the fermion action down to the same level as that from the gauge action.

The advantages of Wilson fermions are their theoretical simplicity and relatively low computational cost. Their main disadvantage is the lack of chiral symmetry, which makes them difficult to use in cases where mixing with wrong chirality operators can occur, particularly if this involves divergences proportional to powers of $1/a$. A related problem is the presence of potential numerical instabilities due to spurious near-zero modes of the lattice Dirac operator. There are, however,

studies that successfully ameliorate the problems due to the lack of chiral symmetry and increase the range of quantities for which Wilson fermions can be used (see, e.g., Refs. [11–13]).

Twisted-mass fermions [14] are a variant of Wilson fermions in which two flavors are treated together with an isospin-breaking mass term (the “twisted mass” term). The main advantage of this approach is that all errors linear in a are automatically removed (without the need for tuning of parameters) by a clever choice of twisted mass and operators [15]. A disadvantage is the presence of isospin breaking effects (such as a splitting between charged and neutral pion masses even when up and down quarks are degenerate), which, however, vanish as $a^2\Lambda^2$ in the continuum limit. Strange and charm quarks can be added as a second pair, with a term added to split their masses [16,17].

Staggered fermions are a reduced version of naive fermions in which there is only a single fermion Dirac component on each lattice site, with the full Dirac structure built up from neighboring sites [18]. They have the advantages of being somewhat faster to simulate than Wilson-like fermions, of preserving some chiral symmetry, and of having discretization errors of $\mathcal{O}(a^2)$. Their disadvantage is that they retain some of the doublers (3 for $d = 4$). The action thus describes four degenerate fermions in the continuum limit. These are usually called “tastes”, to distinguish them from physical flavors, and the corresponding SU(4) symmetry is referred to as the “taste symmetry”. The preserved chiral symmetry in this formulation has non-singlet taste. Practical applications usually introduce one staggered fermion for each physical flavor, and remove contributions from the unwanted tastes by taking the fourth-root of the fermion determinant appearing in the path integral. The validity of this “rooting” procedure is not obvious because taste symmetry is violated for non-zero lattice spacing. Theoretical arguments, supported by numerical evidence, suggest that the procedure is valid as long as one takes the continuum limit before approaching the light quark mass region [19]. Additional issues arise for the valence quarks (those appearing in quark propagators, as described in Sec. 17.2 below), where rooting is not possible, and one must ignore the extra tastes, or account for them by including appropriate factors [20], which can be nontrivial in applications involving baryons [21].

Just as for Wilson fermions, the staggered action can be improved, so as to reduce discretization errors. The Asqtad (a -squared tadpole improved) action [22] was used until recently in many large scale simulations [23]. More recent calculations use the HISQ (highly improved staggered quark) action, introduced in Ref. [24]. At tree-level it removes both $\mathcal{O}(a^2)$ errors and, to lowest order in the quark speed v/c , $\mathcal{O}([am]^4)$ errors. It also substantially reduces effects caused by taste-symmetry breaking. This makes it attractive not only for light quarks, but means that it is also quite accurate for heavy quarks because it suppresses $(am)^n$ errors. It is being used to directly simulate charm quarks and to approach direct simulations of bottom quarks (for early studies, see, e.g., [25–27]).

There is an important class of lattice fermions, “Ginsparg-Wilson fermions,” that possess a continuum-like chiral symmetry without introducing unwanted doublers. The lattice Dirac operator D for these fermions satisfies the Ginsparg-Wilson relation $D\gamma_5 + \gamma_5 D = aD\gamma_5 D$ [28]. In the continuum, the right-hand-side vanishes, leading to chiral symmetry. On the lattice, it is non-vanishing, but with a particular form (with two factors of D) that restricts the violations of chiral symmetry in Ward-Takahashi identities to short-distance terms that do not contribute to physical matrix elements [29]. In fact, one can define a modified chiral transformation on the lattice (by including dependence on the gauge fields) such that Ginsparg-Wilson fermions have an exact chiral symmetry for on-shell quantities [30]. The net result is that such fermions essentially have the same properties under chiral transformations as do continuum fermions, including the index theorem [29]. Their leading discretization errors are of $\mathcal{O}(a^2)$.

Two types of Ginsparg-Wilson fermions are currently being used in large-scale numerical simulations. The first is Domain-wall fermions (DWF). These are defined on a five-dimensional space, in which the fifth dimension is fictitious [31]. The action is chosen so that the low-lying modes are

chiral, with left- and right-handed modes localized on opposite four-dimensional surfaces. For an infinite fifth dimension, these fermions satisfy the Ginsparg-Wilson relation. In practice, the fifth dimension is kept finite, and there remains a small, controllable violation of chiral symmetry. The second type is Overlap fermions. These appeared from a completely different context and have an explicit form that exactly satisfies the Ginsparg-Wilson relation [32]. Their numerical implementation requires an approximation of the matrix sign function of a Wilson-like fermion operator, and various approaches are being used. In fact, it is possible to rewrite these approximations in terms of a five-dimensional formulation, showing that the DWF and Overlap approaches are essentially equivalent [33,34]. Numerically, the five-dimensional approach appears to be more computationally efficient.

The various lattice fermion formulations are often combined with the technique of link smearing. Here one couples the fermions to a smoother gauge link, defined by averaging with adjacent links in a gauge invariant manner. Several closely related implementations are being used. All reduce the coupling of fermions to the short-distance fluctuations in the gauge field, leading to an improvement in the numerical stability and speed of algorithms. One cannot perform this smearing too aggressively, however, since the smearing may distort short distance physics and enhance discretization errors.

As noted above, each fermion formulation has its own advantages and disadvantages. For instance, domain-wall and overlap fermions are theoretically preferred as they have chiral symmetry without doublers, but their computational cost is greater than for other choices. If the physics application of interest and the target precision do not require near-exact chiral symmetry, there is no strong motivation to use these expensive formulations. On the other hand, there is a class of applications (including the calculation of the $\Delta I = 1/2$ amplitude for $K \rightarrow \pi\pi$ decays [35–37] and the S -parameter [38]) where chiral symmetry plays an essential role and for which the use of Ginsparg-Wilson fermions is strongly favored.

17.1.3 Heavy quarks on the lattice

The fermion formulations described in the previous subsection can be used straightforwardly only for quarks whose masses are small compared to the lattice cutoff, $m_q \lesssim 1/a$. This is because there are discretization errors proportional to powers of am_q , and if $am_q \gtrsim 1$ these errors are large and uncontrolled. Present LQCD simulations typically have cutoffs in the range of $1/a = 2\text{--}5$ GeV (corresponding to $a \approx 0.1\text{--}0.04$ fm). Thus, while for the up, down and strange quarks one has $am_q \ll 1$, for bottom quarks (with $m_b \approx 4.5$ GeV) one must use alternative approaches. Charm quarks ($m_c \approx 1.5$ GeV) are an intermediate case, allowing simulations using both direct and alternative approaches, although increasingly the direct approach is being used.

For the charm quark, the straightforward approach is to simultaneously reduce the lattice spacing and to improve the fermion action so as to reduce the size of errors proportional to powers of am_c . This approach has been followed successfully using the HISQ, twisted-mass and domain-wall actions [24, 25, 27, 39–41]. It is important to note, however, that reducing a increases the computational cost because an increased number of lattice points are needed for the same physical volume. One cannot reduce the spatial size below 2–3 fm without introducing significant finite volume errors. Present lattices have typical sizes of $\sim 64^3 \times 128$ (with the long direction being Euclidean time), and thus allow a lattice cutoff up to $1/a \sim 4\text{--}6$ GeV.

This approach can, to some extent, be extended to the bottom quark, by the use of simulations with small lattice spacings [26, 42]. This has been pursued with the HISQ action [43], using lattices of size up to $144^3 \times 288$ and lattice spacings down to $a \approx 0.03$ fm ($1/a \approx 6.6$ GeV). Extrapolation in m_b is still needed [44], however, and this makes use of the mass dependence predicted by Heavy Quark Effective Theory (HQET). Small lattice spacings are also helpful for the simulations of

quarkonium for which a different heavy-quark mass scaling is expected. See Ref. [45] for a recent study.

Alternative approaches for discretizing heavy quarks are motivated by effective field theories. For a bottom quark in heavy-light hadrons, one can use HQET to expand about the infinite quark-mass limit. In this limit, the bottom quark is a static color source, and one can straightforwardly write the corresponding lattice action [46]. Corrections, proportional to powers of $1/m_b$, can be introduced as operator insertions, with coefficients that can be determined non-perturbatively using existing techniques [47]. This method allows the continuum limit to be taken controlling all $1/m_b$ corrections.

Another way of introducing the $1/m_b$ corrections is to include the relevant terms in the effective action. This leads to a non-relativistic QCD (NRQCD) action, in which the heavy quark is described by a two-component spinor [48]. This approach has the advantage over HQET that it can also be used for heavy-heavy systems, such as the Upsilon states. Moreover, the bottom quark can be treated without any extrapolation in m_b . A disadvantage is that some of the parameters in this effective theory are determined perturbatively (at tree-level or at one-loop [49]), which limits the precision of the final results. Although discretization effects can be controlled with good numerical precision for a range of lattice spacings, these artifacts cannot be extrapolated away by taking the lattice spacing to zero. This is because NRQCD is a non-relativistic effective field theory and so ceases to work when the cutoff π/a becomes much larger than the heavy-quark mass. In practice these effects are accounted for in the error budget.

This problem can be avoided if one uses HQET power counting to analyze and reduce discretization effects for heavy quarks while using conventional fermion actions [50]. For instance, one can tune the parameters of an improved Wilson quark action so that the leading HQET corrections to the static quark limit are correctly accounted for. As the lattice spacing becomes finer, the action smoothly goes over to that of a light Wilson quark action, where the continuum limit can be taken as usual. In principle, one can improve the action in the heavy quark regime up to arbitrarily high orders using HQET, but so far large-scale simulations have typically used clover improved Wilson quarks, where tuning the parameters of the action corresponds to including all corrections through next-to-leading order in HQET. Three different methods for tuning the parameters of the clover action are being used: the Fermilab [50], Tsukuba [51] and Columbia [52] approaches. An advantage of this HQET approach is that the c and b quarks can be treated on the same footing. Parameter tuning has been done perturbatively, as in NRQCD, or using non-perturbative tuning of some of the parameters [53, 54]. One can improve the effective theory including the terms beyond the next-to-leading order. The Oktay-Kronfeld action that includes dimension-six and -seven operators has been constructed [55] and used in large-scale numerical calculations [56].

Another approach is the “ratio method” introduced in Ref. [57]. Here one uses quarks with masses lying at, or slightly above, the charm mass m_c , which can be simulated with a relativistic action, and extrapolates to m_b incorporating the behavior predicted by HQET. The particular implementation relies on the use of ratios. As an example, consider the B meson decay constant f_B . According to HQET, this scales as $1/\sqrt{m_B}$ for $m_B \gg \Lambda_{\text{QCD}}$, up to a logarithmic dependence that is calculable in perturbative QCD (but will be suppressed in the following). Here m_B is the B meson mass, which differs from m_b by $\sim \Lambda_{\text{QCD}}$. One considers the ratio $y(\lambda, m_{b'}) \equiv f_{B''} \sqrt{m_{B''}} / f_{B'} \sqrt{m_{B'}}$ for fictitious B mesons containing b quarks with unphysical masses $m_{b'}$ and $m_{b''} = \lambda m_{b'}$. HQET implies that $y(\lambda, m_{b'})$ approaches unity for large $m_{b'}$ and any fixed $\lambda > 1$. The ratios are evaluated on the lattice for the sequence of masses $m_{b'} = m_c, \lambda m_c, \lambda^2 m_c$, all well below the physical m_b , and for each the continuum limit is taken. The form of the ratio for larger values of $m_{b'}$ is obtained by fitting, incorporating the constraints implied by HQET. The result for $f_B \sqrt{m_B}$ is then obtained as a product of y 's with $f_D \sqrt{m_D}$ [58].

17.1.4 QED on the lattice

Quarks in nature are electrically charged, and the resultant coupling to photons leads to shifts in the properties of hadrons that are generically of $\mathcal{O}(\alpha_{\text{EM}})$. Thus, for example, the proton mass is increased by ~ 1 MeV relative to that of the neutron due to its overall charge although this effect is more than compensated for by the ~ 2.5 MeV relative decrease due to the up quark being lighter than the down quark [59]. This example shows that once pure QCD, isospin-symmetric lattice calculations reach percent-level accuracy, further improvement requires the inclusion of effects due to both electromagnetism and the up-down mass difference. This level of accuracy has in fact been obtained for various quantities, e.g., light hadron masses and decay constants (see Ref. [60]), and simulations including isospin-breaking and QED effects are becoming more common.

One approach for including QED is to treat electromagnetic gauge fields in a similar fashion to those of QCD. This extension is straightforward, although some new subtleties arise. The essential change is that the quark must now propagate through a background field containing both gluons and photons. The gauge field U_μ that appears in the covariant derivative of Eq. (17.3) is extended from an SU(3) matrix to one living in U(3): $U_\mu \rightarrow U_\mu e^{iaq_e A_\mu^{\text{EM}}}$. Here A_μ^{EM} is the photon field, e the electromagnetic coupling, and q the charge of the quark, e.g., $q = 2/3$ for up and $-1/3$ for down and strange quarks. The lattice action for the photon that is typically used is a discretized version of the continuum action Eq. (17.2), rather than the form used for the gluons, Eq. (17.1). This “non-compact” action has the advantage that it is quadratic in A_μ^{EM} , which simplifies the QED part of the generation of configurations.

One subtlety that arises is that Gauss’ law forbids a charged particle in a box with periodic boundary conditions. This can be overcome by including a uniform background charge, which can be shown to be equivalent to removing the zero-momentum mode from the photon field, an approach denoted QED_L [61]. However, this modification leads to enhanced finite-volume dependence for physical quantities, scaling as $1/L^n$ with $n = 1, 2, \dots$. This should be compared to the $\exp(-m_\pi L)$ dependence expected for many quantities (as discussed in Sec. 17.1.6.2 below). Methods to remove the leading few powers of $1/L$ have been developed [62, 63], and there is a promising alternative approach in which QED effects are calculated analytically in infinite volume [64]. Finally we note that there is an alternative approach using so-called C^* boundary conditions that avoids the Gauss’ law issue altogether, although the numerical application is still at an early stage [65, 66].

Substantial progress on including QED and isospin-breaking effects has been made over the last few years. The direct approach of using different up and down-quark masses and simulating QED has been successfully carried out for a range of quark masses approaching the physical values [59, 67–69]. Alternative approaches have also been used: reweighting the QCD fields *a posteriori* [70], using a massive photon [71], and keeping only the linear term in an expansion in α_{EM} about the QCD only case [72, 73], with the latter approach by now the most popular. Most calculations to date have included QED effects for the valence quarks but not the sea quarks (the “electro-quenched approximation”). [41, 74–77].

The QED corrections to processes including leptons, such as the leptonic and semileptonic decays of hadrons, involve additional diagrams in which a photon propagator bridges between a hadron and a lepton. Such diagrams induce infrared divergences that cancel against soft photon radiation (Bloch-Nordsieck theorem [78]). Methods have been developed to implement this cancellation in lattice calculations, treating the soft photon analytically [62], and results have been reported for leptonic pion and kaon decays [79–81]. An application to semi-leptonic decays has been developed [64, 82].

17.1.5 Basic inputs for lattice calculations

Since LQCD is nothing but a regularization of QCD, the renormalizability of QCD implies that the number of input parameters in LQCD is the same as for continuum QCD—the strong gauge coupling $\alpha_s = g^2/(4\pi)$, the quark masses for each flavor, and the CP violating phase θ . The θ parameter is usually assumed to be zero, while the other parameters must be determined using experimental inputs.

17.1.5.1 Lattice spacing

In QCD, the gauge coupling is a function of scale. With lattice regularization, this scale is the inverse lattice spacing $1/a$, and choosing the bare gauge coupling is equivalent to fixing the lattice spacing.

In principle, a can be determined using any dimensionful quantity measured accurately by experiments. For example, using the mass of hadron H one has $a = (am_H)^{\text{lat}}/m_H^{\text{exp}}$. One chooses quantities that can be calculated accurately on the lattice, and that are only weakly dependent on the quark masses. The latter property minimizes errors from extrapolating or interpolating to the physical light quark masses or from mistuning of other quark masses.

Commonly used choices are the spin-averaged 1S-1P or 1S-2S splittings in the Upsilon system, the masses of the Ξ and Ω^- baryons, and the pion decay constant f_π . Ultimately, all choices must give consistent results for a , and that this is the case provides a highly non-trivial check of both the calculational method and of QCD.

Many recent lattice calculations use intermediate length scales in place of a direct determination of the lattice spacing. These length scales, which we denote \mathcal{R} , have the advantage that they can be precisely, and relatively cheaply, computed numerically. Examples are r_0 , derived from the heavy quark potential [83], and t_0 and w_0 , determined from the gradient flow of the gauge field [84]. These scales are used in the following manner, explained here in the context of calculating a quantity Q with mass dimension d (e.g. a decay constant for which $d = 1$). In the first step, one calculates the dimensionless quantities $a^d Q$ and \mathcal{R}/a in a given lattice calculation, and forms the product $(a^d Q) \times (\mathcal{R}/a)^d = Q\mathcal{R}^d$. In a second step, one uses results available from previous dedicated lattice calculations that have determined \mathcal{R} in physical units (i.e. fm) by relating them to physical quantities as discussed above. Then one obtains $Q = (Q\mathcal{R}^d)/\mathcal{R}^d$. The use of intermediate quantities is reviewed in the latest edition of the Flavor Lattice Averaging Group (FLAG) report [85].

17.1.5.2 Light quark masses

In LQCD simulations, the up, down and strange quarks are usually referred to as the light quarks, in the sense that $m_q < \Lambda_{\text{QCD}}$. (The standard definition of Λ_{QCD} is given in the “Quantum Chromodynamics” review; in this review we are using it only to indicate the approximate non-perturbative scale of QCD.) This condition is stronger than that used above to distinguish quarks with small discretization errors, $m_q < 1/a$. Loop effects from light quarks must be included in the simulations to accurately represent QCD. At present, most simulations are done in the isospin symmetric limit $m_u = m_d \equiv m_\ell < m_s$, with charm-quark loops either excluded (referred to as “ $N_f = 2 + 1$ ” simulations) or included (denoted “ $N_f = 2 + 1 + 1$ ” simulations). As noted above, precision is now reaching the point where isospin breaking effects must be included. To do so without approximation requires simulating with non-degenerate up and down quarks (leading to $N_f = 1 + 1 + 1$ or $1 + 1 + 1 + 1$ simulations) as well as including electromagnetism (as described above).

We now describe the tuning of m_ℓ , m_s and m_c to their physical values. (For brevity, we ignore isospin violation in the following discussion.) The most commonly used quantities for these tunings are, respectively, m_π , m_K and m_{η_c} . If the scale is being set by m_Ω , then one adjusts the lattice quark masses until the ratios m_π/m_Ω , m_K/m_Ω and m_{η_c}/m_Ω take their physical values. In the past,

most calculations needed to extrapolate to the physical value of m_ℓ (typically using forms based on chiral perturbation theory [ChPT]), while simulating directly at or near to the physical values of m_s and m_c . Present calculations are increasingly done with physical or near physical values of m_ℓ , requiring at most only a short extrapolation or interpolation.

17.1.5.3 Heavy quark masses

The b quark is usually treated only as a valence quark, with no loop effects included. The errors introduced by this approximation can be estimated to be $\sim \alpha_s(m_b)\Lambda_{\text{QCD}}^2/m_b^2$ and are likely to be very small. In the past, the same approximation has been made for the c quark, leading to errors $\sim \alpha_s(m_c)\Lambda_{\text{QCD}}^2/m_c^2$. (See Ref. [86] for a quantitative estimate of the effects of including the charm quark on some low energy physical quantities, and Ref. [87] for similar estimates for B -meson matrix elements.) For high precision, however, dynamical charm quarks are necessary, and some of the most recent simulations now include them.

The b quark mass can be tuned by setting heavy-heavy (\mathcal{R}) or heavy-light (B) meson masses to their experimental values. Consistency between these two determinations provides an important check that the determination of parameters in the heavy quark lattice formulations is being done correctly (see, e.g., Ref. [26, 88, 89]). For instance, the b quark masses obtained from heavy-light [44] and heavy-heavy [77] mesons are in excellent agreement within the precision of 0.5%.

17.1.6 Sources of systematic error

Lattice results have statistical and systematic errors that must be quantified for any calculation in order for the result to be a useful input to phenomenology. The statistical error is due to the use of Monte Carlo importance sampling to evaluate the path integral (a method discussed below). There are, in addition, a number of systematic errors that are always present to some degree in lattice calculations, although the size of any given error depends on the particular quantity under consideration and the parameters of the ensembles being used. The most common lattice errors are reviewed below.

Although not strictly a systematic error, it is important to note that the presence of long auto-correlations in the sequence of lattice configurations generated by the Monte Carlo method can lead to underestimates of statistical errors [90]. It is known that the global topological charge of the gauge fields decorrelates very slowly with certain algorithms [90, 91]. The effect of poorly sampling topological charge is expected to be most significant for the pion mass and related quantities [92–94]. This issue becomes more relevant as the precision of the final results improves. The problem of slow decorrelation of topology can be mitigated using open boundary conditions, for which the global topological charge is not quantized [95].

17.1.6.1 Continuum limit

Physical results are obtained in the limit that the lattice spacing a goes to zero. The Symanzik effective theory (SET) determines the scaling of lattice artefacts with a . Most lattice calculations use improved actions with leading discretization errors of $\mathcal{O}(\alpha_s a\Lambda)$, $\mathcal{O}(a^2\Lambda^2)$, or $\mathcal{O}(\alpha_s a^2\Lambda^2)$, where Λ is a typical momentum scale in the system. Knowledge of the scaling of the leading discretization errors allows controlled extrapolation to $a = 0$ when multiple lattice spacings are available, as in current state-of-the-art calculations. Residual errors arise from the exclusion of sub-leading a dependence from the fits, either that due to prefactors containing powers of $\log(a)$, or from higher powers of a . The former can, in principle, be understood using the SET, and first studies of this have been undertaken [96–98].

For many quantities the typical momentum scale in the system is $\sim \Lambda_{\text{QCD}} \approx 300$ MeV. Discretization errors are expected to be larger for quantities involving larger scales, for example form factors or decays involving particles with momenta or masses larger than Λ_{QCD} .

17.1.6.2 Infinite volume limit

LQCD calculations are necessarily carried out in finite space-time boxes, leading to departures of physical quantities (masses, decay constants, etc.) from their measured, infinite volume values. These finite-volume shifts are an important systematic that must be estimated and minimized.

Typical lattices are asymmetric, with N_s points in the three spatial directions and N_t in the (Euclidean) temporal direction. The spatial and temporal sizes in physical units are thus $L_s = aN_s$ and $L_t = aN_t$, respectively. (Anisotropic lattice spacings are also sometimes used, as discussed below in Sec. 17.2.2.) Typically, $L_t \geq 2L_s$, a longer temporal direction being used to allow excited-state contributions to correlators to decay. This means that the dominant impact of using finite volume is from the presence of a finite spatial box.

The highest-precision LQCD calculations are of quantities involving no more than a single strongly-interacting particle in initial and final states. For such quantities, once the volume exceeds about 2 fm (so that the particle is not “squeezed”), the dominant finite-volume effect comes from virtual pions wrapping around the lattice in the spatial directions. This effect is exponentially suppressed as the volume becomes large, roughly as $\sim \exp(-m_\pi L_s)$, and has been estimated using ChPT [99] or other methods [100]. These estimates suggest that finite volume shifts are sub-percent effects when $m_\pi L_s \gtrsim 4$, and most large-scale simulations use lattices satisfying this condition. (See also Sec. 2.1.1 of the FLAG report [85] for more detailed discussion concerning the conditions required to control finite volume effects.) This becomes challenging as one approaches the physical pion mass, for which $L_s \gtrsim 5$ fm is required.

Finite volume errors are usually determined by repeating the simulations on two or more different volumes (with other parameters fixed). If different volumes are not available, the ChPT estimate can be used, often inflated to account for the fact that the ChPT calculation is truncated at some order.

In the future, LQCD calculations involving more than a single hadron will become increasingly precise. Examples include the calculation of resonance parameters and the $K \rightarrow \pi\pi$ amplitudes. Finite volume effects are much larger in these cases, with power-law terms (e.g., $1/L_s^3$) in addition to exponential dependence. Indeed, as will be discussed in Sec. 17.2.4, one can use the volume dependence to indirectly extract infinite-volume quantities such as scattering lengths. Doing so, however, requires a set of lattice volumes satisfying $m_\pi L_s \gtrsim 4$ and is thus more challenging than for single-particle quantities.

17.1.6.3 Chiral extrapolation

Until recently, an important source of systematic error in LQCD calculations was the need to extrapolate in m_u and m_d (or, equivalently, in m_π). This extrapolation was usually done using functional forms based on ChPT, or with analytic functions, with the difference between different fits used as an estimate of the systematic error, which was often substantial. Increasingly, however, calculations work directly at, or very close to, the physical quark masses. This either removes entirely, or greatly reduces, the uncertainties in the extrapolation, such that this error is subdominant.

17.1.6.4 Operator matching

Many of the quantities that LQCD can precisely calculate involve hadronic matrix elements of operators from the electroweak Hamiltonian. Examples include the pion and kaon decay constants, semileptonic form factors and the kaon mixing parameter B_K (the latter defined in Eq. (17.13)). The operators in the lattice matrix elements are defined in the lattice regularization scheme. To be used in tests of the Standard Model, however, they must be matched to the continuum regularization scheme in which the corresponding Wilson coefficients have been calculated. The only case in which such matching is not needed is if the operator is a conserved or partially conserved current. Similar

matching is also needed for the conversion of lattice bare quark masses to those in the continuum $\overline{\text{MS}}$ scheme.

Several methods are used to calculate the matching factors: perturbation theory (usually to one- or two-loop order), non-perturbative renormalization (NPR) using Landau-gauge quark and gluon external states [101], NPR using gauge-invariant methods based on the Schrödinger functional [102], NPR using gauge-invariant short-distance hadron correlators [103], and NPR using gauge-invariant heavy-heavy correlators [27, 104]. The NPR methods replace truncation errors (which can only be approximately estimated) by statistical and systematic errors that can be determined reliably and systematically reduced.

An issue that arises in some of such calculations (e.g., for quark masses and B_K) is that, using NPR with Landau-gauge quark and gluon external states, one ends up with operators regularized in a MOM-like scheme (or a Schrödinger-functional scheme), rather than the $\overline{\text{MS}}$ scheme mostly used for calculating the Wilson coefficients. To make contact with this scheme requires a purely continuum perturbative matching calculation supplemented by the operator product expansion (OPE). (The importance of power corrections is emphasized in [105].) The resultant truncation error of perturbative expansion and OPE can be minimized by pushing up the momentum scale at which the matching is done using step-scaling techniques as part of the NPR calculation [106].

It should also be noted that this final step in the conversion to the $\overline{\text{MS}}$ scheme could be avoided if continuum calculations used a MOM-like scheme or if one imposes a renormalization condition for quantities that are calculable both in the $\overline{\text{MS}}$ scheme and in LQCD, such as the hadron correlators at short distances (see, e.g., Ref. [107]).

17.2 Methods and status

Once the lattice action is chosen, it is straightforward to define the quantum theory using the path integral formulation. The Euclidean-space partition function is

$$Z = \int [dU] \prod_f [dq_f][d\bar{q}_f] e^{-S_g[U] - \sum_f \bar{q}_f (D[U] + m_f) q_f}, \quad (17.4)$$

where link variables are integrated over the $\text{SU}(3)$ manifold, q_f and \bar{q}_f are Grassmann (anti-commuting) quark and antiquark fields of flavor f , and $D[U]$ is the chosen lattice Dirac operator with m_f the quark mass in lattice units. Integrating out the quark and antiquark fields, one arrives at a form suitable for simulation:

$$Z = \int [dU] e^{-S_g[U]} \prod_f \det(D[U] + m_f). \quad (17.5)$$

The building blocks for calculations are expectation values of multi-local gauge-invariant operators, also known as “correlation functions”,

$$\langle \mathcal{O}(U, q, \bar{q}) \rangle = (1/Z) \int [dU] \prod_f [dq_f][d\bar{q}_f] \mathcal{O}(U, q, \bar{q}) e^{-S_g[U] - \sum_f \bar{q}_f (D[U] + m_f) q_f}. \quad (17.6)$$

If the operators depend on the (anti-)quark fields q_f and \bar{q}_f , then integrating these fields out leads not only to the fermion determinant but also, through Wick’s theorem, to a series of quark “propagators”, $(D[U] + m_f)^{-1}$, connecting the positions of the fields.

This set-up allows one to choose, by hand, the masses of the quarks in the determinant (the sea quarks) differently from those in the propagators (valence quarks). This is called “partial quenching”, and is used by some calculations as a way of obtaining more data points from which to extrapolate both sea and valence quarks to their physical values.

17.2.1 Monte-Carlo method

Since the number of integration variables U is huge ($N_s^3 \times N_t \times 4 \times 8$), direct numerical integration is impractical and one has to use Monte-Carlo techniques. In this method, one generates a Markov chain of gauge configurations (a “configuration” being the set of U ’s on all links) distributed according to the probability measure $[dU]e^{-S_g[U]} \prod_f \det(D[U] + m_f)$. Once the configurations are generated, expectation values $\langle \mathcal{O}(U, q, \bar{q}) \rangle$ are calculated by averaging over those configurations. In this way the configurations can be used for many different calculations, and there are several large collections of ensembles of configurations (with a range of values of a , lattice sizes and quark masses) that are publicly available through the International Lattice Data Grid (ILDG) [108]. As the number of the configurations, N , is increased, the error decreases as $1/\sqrt{N}$.

The most challenging part of the generation of gauge configurations is the need to include the fermion determinant. Direct evaluation of the determinant is not feasible, as it requires $\mathcal{O}((N_s^3 \times N_t)^3)$ computations. Instead, one rewrites it in terms of “pseudo-fermion” fields ϕ (auxiliary fermion fields with bosonic statistics). For example, for two degenerate quarks one has

$$\det(D[U] + m_f)^2 = \int [d\phi] e^{-\phi^\dagger (D[U] + m_f)(D[U] + m_f)^\dagger^{-1} \phi}. \quad (17.7)$$

By treating the pseudo-fermions as additional integration variables in the path integral, one obtains a totally bosonic representation. The price one pays is that the pseudo-fermion effective action is highly non-local since it includes the inverse Dirac operator $(D[U] + m_f)^{-1}$. Thus, the large sparse matrix $(D[U] + m)$ has to be inverted every time one needs an evaluation of the effective action.

Present simulations generate gauge configurations using the Hybrid Monte Carlo (HMC) algorithm [109], or variants thereof. This algorithm combines molecular dynamics (MD) evolution [110–112] in a fictitious time (which is also discretized) with a Metropolis “accept-reject” step [113]. It makes a global update of the configuration, and is made exact by the Metropolis step. In its original form it can be used only for two degenerate flavors, but extensions (particularly the rational HMC [114]) are available for single flavors. Considerable speed-up of the algorithms has been achieved over the last two decades using a variety of techniques.

All these algorithms spend the bulk of their computational time on the repeated inversion of $(D[U] + m)$ acting on a source (which is required at every step of the MD evolution). Inversions are done using a variety of iterative algorithms, e.g., the conjugate gradient algorithm. In this class of algorithms, computational cost is determined by the condition number of the matrix, which is the ratio of maximum and minimum eigenvalues. For $(D[U] + m)$ the smallest eigenvalue is $\approx m$, and the cost is inversely proportional to the quark mass. This is a major reason why simulations at the physical light quark masses are challenging.

Algorithmic improvements have significantly reduced this problem. The main idea is to separate different length scales [115, 116]. Since the low eigenvalues of $(D[U] + m)$ are associated with long wavelength quark modes, one may project the problem onto that of a coarse-grained lattice by averaging the field within a block of sublattices and carrying out the inversion on this coarse lattice. The result is then fed back to the original lattice as an efficient *preconditioner* for the iterative solver, and the whole procedure may be nested multiple times. Variants of such methods have been implemented, specifically domain-decomposition [117, 118], deflation [119–122] and multigrid [123, 124]. They are increasingly used in large-scale lattice simulations.

A practical concern is the inevitable presence of correlations between configurations in the Markov chain. These are characterized by an auto-correlation length in the fictitious MD time. One aims to use configurations separated in MD time by greater than this auto-correlation length. In practice, it is difficult to measure this length accurately, see, e.g., [125], and this leads to some uncertainty in the resulting statistical errors, as well as the possibility of insufficient equilibration.

The computational cost of gauge generation grows with the lattice volume, $V_{\text{lat}} = N_s^3 N_t$, as $V_{\text{lat}}^{1+\delta}$. Here $\delta = 1/4$ for the HMC algorithm [126] and can be reduced slightly using modern variants. Such growth with V_{lat} provides a (time-dependent) limit on the largest lattice volumes that can be simulated. At present, the largest lattices being used have $N_s = 144$ and $N_t = 288$ or $N_s = N_T = 160$. Typically, one aims to create an ensemble of $\sim 10^3$ statistically independent configurations at each choice of parameters (a , m_q and V_{lat}). For most physical quantities of interest, this is sufficient to make the resulting statistical errors smaller than or comparable to the systematic errors. Recently, the master-field approach is being investigated [13, 127, 128]. It aims to create a large-volume ensemble and repeat the calculation of physical quantities in different small patches of the entire lattice. Translational invariance guarantees that the correct average is obtained with fewer configurations than in the traditional approach, with the advantage of reduced finite-volume effects [129].

In the past, the cost of generating gauge configurations was larger than that of performing “measurements” on those configurations. However, as the number of quantities being calculated and their complexity has increased, the balance has shifted to the point that the total cost of measurements exceeds that of generation. Sharing the configurations, e.g. through the ILDG, has become more common, and a number of groups are utilizing them to compute a wide variety of quantities, as partly covered by the following sections.

17.2.2 Two-point functions

One can extract properties of stable hadrons from two-point correlation functions, $\langle O_X(x)O_Y^\dagger(0) \rangle$. Here $O_{X,Y}(x)$ are operators that have non-zero overlaps with the hadronic state of interest $|H\rangle$, *i.e.* $\langle 0|O_{X,Y}(x)|H\rangle \neq 0$. On the lattice, the two-point correlation function can be constructed, using Wick’s theorem, from the quark propagators $(D[U] + m_f)_{x_0}^{-1}$ from the insertion point of the source operator $O_Y(0)$ to the sink operator $O_X(x)$. An average over gauge configurations yields the estimate of $\langle O_X(x)O_Y^\dagger(0) \rangle$.

One usually Fourier transforms in the spatial directions and considers correlators as a function of Euclidean time:

$$C_{XY}(t; \mathbf{p}) = \sum_{\mathbf{x}} \langle O_X(t, \mathbf{x})O_Y^\dagger(0) \rangle e^{-i\mathbf{p}\cdot\mathbf{x}}. \quad (17.8)$$

(Here and throughout this section all quantities are expressed in dimensionless lattice units, so that, for example, $\mathbf{p} = a\mathbf{p}_{\text{phys}}$.) By inserting a complete set of states having spatial momentum \mathbf{p} , the two-point function can be written as

$$C_{XY}(t; \mathbf{p}) = \sum_{i=0}^{\infty} \frac{1}{2E_i(\mathbf{p})} \langle 0|O_X(0)|H_i(\mathbf{p}) \rangle \langle H_i(\mathbf{p})|O_Y^\dagger(0)|0 \rangle e^{-E_i(\mathbf{p})t}, \quad (17.9)$$

where the energy of the i -th state $E_i(\mathbf{p})$ appears in the eigenvalue of the Euclidean time evolution operator e^{-Ht} , $e^{-E_i(\mathbf{p})t}$. The factor of $1/[2E_i(\mathbf{p})]$ is due to the relativistic normalization used for the states. For large enough t , the dominant contribution is that of the lowest energy state $|H_0(\mathbf{p})\rangle$:

$$C_{XY}(t) \xrightarrow{t \rightarrow \infty} \frac{1}{2E_0(\mathbf{p})} \langle 0|O_X(0)|H_0(\mathbf{p}) \rangle \langle H_0(\mathbf{p})|O_Y^\dagger(0)|0 \rangle e^{-E_0(\mathbf{p})t}. \quad (17.10)$$

One can thus obtain the energy $E_0(\mathbf{p})$, which equals the hadron mass m_H when $\mathbf{p} = 0$, and the product of matrix elements $\langle 0|O_X(0)|H_i(\mathbf{p}) \rangle \langle H_i(\mathbf{p})|O_Y^\dagger(0)|0 \rangle$.

This method can be used to determine the masses of all the stable (in QCD) mesons and baryons by making appropriate choices of operators. For example, if one uses the axial current, $O_X = O_Y = A_\mu = \bar{d}\gamma_\mu\gamma_5 u$, then one can determine m_{π^+} from the rate of exponential fall-off, and in addition the decay constant f_π from the coefficient of the exponential.

The expression given in (17.9) for the correlator $C_{XY}(t; \mathbf{p})$ shows how, in principle, one can determine the energies of the excited hadron states having the same quantum numbers as the operators $O_{X,Y}$, by fitting the correlation function to a sum of exponentials, including both ground-state and excited-state contributions. It is important to do this in order to obtain accurate results for the ground-state parameters. To reliably identify excited-state parameters in practice, one often needs to use a large basis of operators with a variety of overlaps, $\langle 0|O|H\rangle$, with the different states, and to adopt a variational approach, such as that of [130]. Use of an anisotropic lattices in which a_t , the lattice spacing in the time direction, is smaller than its spatial counterpart, a_s , allows more temporal samples of the correlation function at small times where there is a signal for excited states. Using these and other technical improvements, extensive excited-state spectra have been obtained [131–136].

A complication arises for states with high spins ($j \geq 4$ for bosons) because the spatial rotation group on the lattice is a discrete subgroup of the continuum group $\text{SO}(3)$. This implies that lattice operators, even when chosen to lie in irreducible representations of the lattice rotation group, have overlap with states that have a number of values of j in the continuum limit [137]. For example $j = 0$ operators can also create mesons with $j = 4$. Methods to overcome this problem in practice are available [131, 138] and have been used successfully.

The two-point function (17.8) contains, in principle, information on all possible states having the quantum numbers of the operator O . Thus, if O is chosen to be a vector current, it can be used to estimate the hadronic vacuum polarization function contribution to the muon anomalous magnetic moment, as discussed in Sec. 17.3.6.

17.2.3 Three-point functions

Hadronic matrix elements needed to calculate semileptonic form factors and neutral meson mixing amplitudes can be computed from three-point correlation functions. We discuss here, as a representative example, the $D \rightarrow K$ amplitude. As in the case of two-point correlation functions one constructs operators O_D and O_K having overlap, respectively, with the D and K mesons. We are interested in calculating the matrix element $\langle K|V_\mu|D\rangle$, with $V_\mu = \bar{c}\gamma_\mu s$ the flavor-changing vector current.

To obtain this, we use the three-point correlator

$$C_{KV_\mu D}(t_x, t_y; \mathbf{p}) = \sum_{\mathbf{x}, \mathbf{y}} \langle O_K(t_x, \mathbf{x}) V_\mu(0) O_D^\dagger(t_y, \mathbf{y}) \rangle e^{-i\mathbf{p}\cdot\mathbf{x}}, \quad (17.11)$$

and focus on the limit $t_x \rightarrow \infty$, $t_y \rightarrow -\infty$. In this example we set the D -meson at rest while the kaon carries three-momentum \mathbf{p} . Momentum conservation then implies that the weak operator V_μ inserts three-momentum $-\mathbf{p}$. Inserting a complete set of states between each pair of operators, we find

$$C_{KV_\mu D}(t_x, t_y; \mathbf{p}) = \sum_{i,j} \frac{1}{2m_{D_i} 2E_{K_j}(\mathbf{p})} e^{-m_{D_i} t_x - E_{K_j}(\mathbf{p}) |t_y|} \times \langle 0|O_K(0)|K_j(\mathbf{p})\rangle \langle K_j(\mathbf{p})|V_\mu(0)|D_i(\mathbf{0})\rangle \langle D_i(\mathbf{0})|O_D^\dagger(0)|0\rangle. \quad (17.12)$$

The matrix element $\langle K_i(\mathbf{p})|V_\mu(0)|D_j(\mathbf{0})\rangle$ can then be extracted, since all other quantities in this expression can be obtained from two-point correlation functions. Typically, one is interested in the weak matrix elements of ground states, such as the lightest pseudo-scalar mesons. In the limit of large separation between the three operators in Euclidean time, the three-point correlation function yields the weak matrix element of the transition between ground states. The extraction of the ground state is not always straightforward, especially when a significant contribution is

expected from states with an extra pion. An example relevant to $B \rightarrow \pi \ell \nu$ decay is discussed in Ref. [139].

From (17.12) the matrix element $\langle K_i(\mathbf{p}) | V_\mu(0) | D_j(\mathbf{0}) \rangle$ is obtained at several discretized values of momentum \mathbf{p} , given by a multiple of $2\pi/L$ in each spatial direction. Each momentum corresponds to a certain value of the momentum transfer $q^2 = (m_D - E_K(\mathbf{p}))^2 - \mathbf{p}^2$. The restriction on the available momentum can be relaxed by introducing twisted boundary conditions [140–142], which are a generalization of (anti-)periodic boundary conditions in the spatial directions that allows a general $U(1)$ phase upon translation by distance L . The choice of phase leads to a quark momentum that does not have to be a multiple of $2\pi/L$. The method has been applied in a number of lattice calculations.

To interpolate in q^2 , the so-called z parametrization [143–146] is often employed. It takes account of the analytic structure of the form factor in the complex q^2 plane, and a polynomial expansion in z is justified.

17.2.4 Scattering amplitudes and resonances

The methods described thus far yield matrix elements involving single, stable particles (where by stable we mean here absolutely stable to strong interaction decays). Most of the particles listed in the Review of Particle Properties are, however, unstable—they are resonances decaying into final states consisting of multiple strongly interacting particles. LQCD simulations cannot directly calculate resonance properties, but methods have been developed to do so indirectly for resonances coupled to two-particle final states in the elastic regime, starting from the seminal work of Lüscher [147].

The difficulty faced by LQCD calculations is that, to obtain resonance properties, or, more generally, scattering phase-shifts, one must calculate multi-particle scattering amplitudes in momentum space and put the external particles on their mass-shells. This requires analytically continuing from Euclidean to Minkowski momenta. Although it is straightforward in LQCD to generalize the methods described above to calculate four- and higher-point correlation functions, one necessarily obtains them at a discrete and finite set of Euclidean momenta. Analytic continuation to $p_E^2 = -m^2$ is then an ill-posed and numerically unstable problem. The same problem arises for single-particle states, but can be largely overcome by picking out the exponential fall-off of the Euclidean correlator, as described above. With a multi-particle state there is no corresponding trick, except for two particles at threshold [148], although recent ideas using smeared correlators and advanced spectral-reconstruction methods offer hope for future progress [149, 150].

What LQCD can calculate are the energies of the eigenstates of the QCD Hamiltonian in a finite box. The energies of states containing two stable particles, e.g., two pions, clearly depend on the interactions between the particles. It is possible to invert this dependence and, with plausible assumptions, determine the scattering phase-shifts at a discrete set of momenta from a calculation of the two-particle energy levels for a variety of spatial volumes [147]. This is a challenging calculation, but it has been carried through in several channels with quark masses approaching physical values. Channels studied include $\pi\pi$ (for $I = 2, 1$ and 0), $\bar{K}K$, $K\pi$, $\pi\omega$, $\pi\phi$, KD , DD^* , $B\pi$, and $N\pi$. For recent comprehensive reviews see [151, 152]. Extensions to nucleon interactions are being actively studied [153]. The formalism has been generalized to three particles (both identical and non-degenerate, and including spin) [154], and has been applied in lattice calculations of $3\pi^+$, $2\pi^+ + K^+$, $\pi^+ + 2K^+$, and $3K^*$ systems [155] as well as to the $I = 1$ three-pion channel [156]. For recent reviews, see [152, 157].

It is also possible to extend the methodology to calculate electroweak decay amplitudes to two particles below the inelastic threshold, e.g., $A(K \rightarrow \pi\pi)$ [158]. Results for both the $\Delta I = 3/2$ and $1/2$ amplitudes with physical quark masses have been obtained [35–37, 159], the former now

including a controlled continuum limit [160]. First results for the CP -violating quantity ϵ' have been obtained [35, 36].

Partial extensions of the formalism above the elastic threshold have been worked out, in particular for the case of multiple two-particle channels [161]. Another theoretical extension is to allow the calculation of form factors between a stable particle and a resonance [162], and between two resonances [163]. The former has been used to calculate the $\gamma\pi \rightarrow \rho$ amplitude, albeit for unphysically large quark masses [164, 165], as well as $\gamma K \rightarrow K^*$ [166]. Finally, the formalism for using LQCD to calculate electroweak decays or transitions to three particles, e.g. $\gamma^* \rightarrow 3\pi$ and $K \rightarrow 3\pi$, has recently been worked out [167, 168].

While a systematic extension to decays with many multi-particle channels, e.g., hadronic B decays, has, however, yet to be formulated, some interesting new ideas have been proposed [150, 169, 170], including a method to compute inclusive decay rates or cross sections [171, 172]. The latter represents the inclusive processes using the Compton amplitude, in which two currents are inserted and all possible final states are created between the two [150]. The relative weight among different final states depends on the Euclidean time separation between the current, from which one can extract the inclusive rates. First calculations have been reported [173, 174]. A related approach has been recently applied to provide a lattice determination of the inclusive semileptonic τ decay rate [175].

17.2.5 Status of LQCD simulations

Until the 1990s, most large-scale lattice simulations were limited to the “quenched” approximation, wherein the fermion determinant is omitted from the path integral. While much of the basic methodology was developed in this era, the results obtained had uncontrolled systematic errors and were not suitable for use in placing precision constraints on the Standard Model. During the 1990s, more extensive simulations including the fermion determinant (also known as simulations with “dynamical” or “sea” quarks) were begun, but with unphysically heavy quark masses ($m_\ell \sim 50 - 100$ MeV), such that the extrapolation to the physical light quark masses was a source of large systematic errors [176]. During the 2000s, advances in both algorithms and computers allowed simulations to reach much smaller quark masses ($m_\ell \sim 10 - 20$ MeV) such that LQCD calculations of selected quantities with all sources of error controlled and small became available. Their results played an important role in constraints on the CKM matrix and other phenomenological analyses. In the last decade, simulations directly at the physical isospin-symmetric light quark masses have become standard, removing the need for a chiral extrapolation and thus significantly reducing the overall error. The present frontier, as noted above, is the inclusion of isospin breaking. This will be needed to push the accuracy of calculations below the percent level.

On a more qualitative level, analytic and numerical results from LQCD have demonstrated that QCD confines color and spontaneously breaks chiral symmetry. Confinement can be seen as a linearly rising potential between heavy quark and anti-quark in the absence of quark loops. Analytically, this can be shown in the strong coupling limit $g_{\text{lat}} \rightarrow \infty$ [1]. At weaker couplings there are precise numerical calculations of the potential that clearly show that this behavior persists in the continuum limit [177–179].

Chiral symmetry breaking was also demonstrated in the strong coupling limit on the lattice [18, 180], and there have been a number of numerical studies showing that this holds also in the continuum limit. The accumulation of low-lying modes of the Dirac operator, which is the analog of Cooper pair condensation in superconductors, has been observed, yielding a determination of the chiral condensate [181–187]. Many relations among physical quantities that can be derived under the assumption of broken chiral symmetry have been confirmed by a number of lattice groups [188].

17.3 Physics applications

In this section we describe the main applications of LQCD that are both computationally mature and relevant for the determination of particle properties.

A general feature to keep in mind is that, since there are many different choices for lattice actions, all of which lead to the same continuum theory, a crucial test is that results for any given quantity are consistent. In many cases, different lattice calculations are completely independent and often have very different systematic errors. Thus, final agreement, if found, is a highly non-trivial check, just as it is for different experimental measurements.

The number, variety and precision of the calculations has progressed to the point that an international collaboration, FLAG, has been formed, which aims to collect all lattice results of relevance for a variety of phenomenologically interesting quantities and provide averages of those results that pass appropriate quality criteria. The averages attempt to account for possible correlations between results (which can arise, for example, if they use common gauge configurations). The quantities considered are those we discuss in this section, with the exception of the hadron spectrum, as well as the intermediate scale-setting quantities discussed earlier. The most recent FLAG review is from 2021 [85] (see also older editions, Refs. [60, 188]). The interested reader can consult this review for very extensive discussions of the details of the calculations and of the sources of systematic errors.

We stress that the results we quote below are those obtained using the physical complement of light quarks (i.e. $N_f = 2 + 1$ or $2 + 1 + 1$ simulations).

17.3.1 Spectrum

The most basic prediction of LQCD is of the hadron spectrum. Once the input parameters are fixed as described in Sec. 17.1.5, the masses or resonance parameters of all other states can be predicted. This includes hadrons composed of light (u , d and s) quarks, as well as heavy-light and heavy-heavy hadrons. It also includes quark-model exotics (e.g., $J^{PC} = 1^{-+}$ mesons) and glueballs. Thus, in principle, LQCD calculations should be able to reproduce many of the experimental results compiled in the Review of Particle Properties. Doing so would test both that the error budgets of LQCD calculations are accurate and that QCD indeed describes the strong interactions in the low-energy domain. The importance of the latter test can hardly be overstated.

What is the status of this fundamental test? As discussed in Sec. 1.2, LQCD calculations are most straightforward for stable, low-lying hadrons. Calculations of the properties of resonances that can decay into only two particles are more challenging, but are becoming standard in the meson sector, with the frontier being decays involving baryons. As noted above, the formalism for resonances decaying to three particles exists, but has yet to be applied to resonant channels other than in pioneering calculations. It is also more technically challenging to calculate masses of flavor singlet states (which can annihilate into purely gluonic intermediate states) than those of flavor non-singlets, although again algorithmic and computational advances have begun to make such calculations accessible, including first calculations that reach physical quark masses [189].

The present status for light hadrons is that fully controlled results are available for the masses of the octet light baryons, while results with less than complete control are available for the decuplet baryon resonances, the vector meson resonances and the η and η' . This is discussed in the “Quark Model” review—see, in particular, Fig. 15.9. In addition, it has been possible to calculate the isospin splitting in light mesons and baryons (due to the up-down mass difference and the incorporation of QED). There are also extensive results for heavy-light (D and B systems) and heavy-heavy (J/ψ and Υ systems). All present results, which are discussed in the “Quark Model” review, are consistent with experimental values, and several predictions have been made. We refer the reader to that review for references to the relevant work.

17.3.2 Decay constants and bag parameters

The pseudo-scalar decay constants can be determined from two-point correlation functions involving the axial-vector current, as discussed in Sec. 17.2.2. The decay constant f_P of a meson P is extracted from the weak matrix element involving the axial-vector current using the definition $\langle 0|A_\mu(x)|P(\mathbf{p})\rangle = f_P p_\mu \exp(-ip \cdot x)$, where p_μ is the momentum of P and $A_\mu(x)$ is the axial-vector current. (In practice, results with the smallest errors are obtained using the pseudo-scalar density $P(x) = \bar{q}(x)\gamma_5 q(x)$ instead of $A_\mu(x)$.) Since they are among the simplest quantities to calculate, decay constants provide good benchmarks for lattice methods, in addition to being important inputs for flavor physics phenomenology in their own right. Results from several lattice groups for the pion and kaon decay constants now have sub-percent errors. The decay constants in the charm and bottom sectors, f_D , f_{D_s} , f_B , and f_{B_s} , have also been calculated using the various heavy quark formulations on the lattice outlined in Sec. 17.1.3. The precision has reached sub-percent errors for charmed mesons, and percent-level errors for bottom mesons. Lattice results for all of these decay constants are discussed in detail in the review “Leptonic Decays of Charged Pseudoscalar Mesons.”

Another important lattice quantity is the kaon bag parameter, B_K , which is needed to turn the precise measurement of CP -violation in kaon mixing into a constraint on the Standard Model. It is defined by

$$\frac{8}{3}m_K^2 f_K^2 B_K(\mu) = \langle \bar{K}^0 | Q_{\Delta S=2}(\mu) | K^0 \rangle, \quad (17.13)$$

where m_K is the kaon mass, f_K is the kaon decay constant, $Q_{\Delta S=2} = \bar{s}\gamma_\mu(1-\gamma_5)d\bar{s}\gamma_\mu(1-\gamma_5)d$ is the four-quark operator of the effective electroweak Hamiltonian and μ is the renormalization scale. The short distance contribution to the electroweak Hamiltonian can be calculated perturbatively, but the hadronic matrix element parameterized by B_K must be computed using non-perturbative methods. In order to be of use to phenomenology, the renormalization factor of the four-quark operator must be matched to a continuum renormalization scheme, e.g., to $\overline{\text{MS}}$, as described in Sec. 17.1.6.4. Determinations with percent-level precision using different fermion actions and $N_f = 2+1$ light sea quarks are now available using DWF [190], staggered fermions [191], DWF valence on staggered sea quarks [192], and Wilson fermions [11]. The results are all consistent, and the present FLAG average is $\hat{B}_K = 0.7625(97)$ [85] for its renormalization group invariant definition (for original papers, see [11, 192–194]).

The bag parameters for B and B_s meson mixing are defined analogously to that for kaon mixing. The B and B_s mesons contain a valence b -quark so that calculations of these quantities must use one of the methods for heavy quarks described above. Calculations have been done using NRQCD [195, 196], the Fermilab formalism [87], and static heavy quarks [197]. All results are consistent. The FLAG averages for the quantities relevant for B_s and B mixing with $N_f = 2+1$, which are based on results from Refs. [87, 195, 197], are $f_{B_s}\sqrt{\hat{B}_{B_s}} = 274(8)$ MeV and $f_B\sqrt{\hat{B}_B} = 225(9)$ MeV, with their ratio (which is somewhat better determined) being $\xi = 1.206(17)$. FLAG also quotes an “average” for $N_f = 2+1+1$, which comes from a single calculation [196] and gives $f_{B_s}\sqrt{\hat{B}_{B_s}} = 256(6)$ MeV, $f_B\sqrt{\hat{B}_B} = 211(6)$ MeV, and $\xi = 1.216(16)$. These are consistent with the $N_f = 2+1$ results at the 2σ level. Errors for quantities involving b quarks are typically larger than those for quantities involving only light quarks, although the difference has steadily decreased in recent years.

For the K , D and B systems, one can also consider the matrix elements of four-fermion operators that arise in beyond-the-standard-model (BSM) theories, which can have a different chiral structure. Knowledge of these matrix elements allows one to constrain the parameters of the BSM theories, and is complementary to direct searches at the LHC. Reliable results are now available from lattice calculations, and are reviewed by FLAG in the case of kaon mixing [85]. Complete results for D and B mixing are presented in Ref. [198, 199] and Ref. [87, 200], respectively.

The results for mixing matrix elements are used in the reviews “The CKM Quark-Mixing Matrix,” and “ $B^0 - \bar{B}^0$ Mixing.”

17.3.3 Form factors ($K \rightarrow \pi\ell\nu$, $D \rightarrow K\ell\nu$, $B \rightarrow \pi\ell\nu$, $B \rightarrow D^{(*)}\ell\nu$, etc.)

Semileptonic decay rates can be used to extract CKM matrix elements once the semileptonic form factors are known from lattice calculations. For example, the matrix element of a pseudo-scalar meson P undergoing semileptonic decay to another pseudo-scalar meson D is mediated by the vector current, and can be written in terms of form factors as

$$\langle D(p_D) | V_\mu | P(p_P) \rangle = f_+(q^2)(p_D + p_P - \Delta)_\mu + f_0(q^2)\Delta_\mu, \quad (17.14)$$

where $q = p_D - p_P$, $\Delta_\mu = (m_D^2 - m_P^2)q_\mu/q^2$ and V_μ is the quark vector current. For K and D meson decays, the shapes of the form factors are well determined by experiment and the value of $f_+(q^2)$ at some reference value of q^2 is needed from the lattice in order to extract CKM matrix elements. Lattice calculations of the form factor shapes may provide further consistency checks. Typically, $f_+(q^2)$ dominates the decay rate, since the contribution from $f_0(q^2)$ is suppressed when the final state lepton is light.

The form factor $f_+(0)$ for $K \rightarrow \pi\ell\nu$ decays is highly constrained by the Ademollo-Gatto theorem [201] and chiral symmetry. Old estimates using chiral perturbation theory combined with quark models quote sub-percent precision [202], though they suffer from some model dependence. Utilizing the constraint from the vector current conservation that $f_+(0)$ is normalized to unity in the limit of degenerate up and strange quark masses, the lattice calculation can be made very precise and has now matched the precision of the phenomenological estimates [203–210]. The present FLAG average (from $N_f = 2 + 1 + 1$ simulations) is $f_+(0) = 0.9698(17)$, based on Refs. [210].

Charmed meson semileptonic decays have been calculated by different groups using methods similar to those used for charm decay constants, and results are steadily improving in precision [211–216]. Charmed baryon decays have also been computed using a similar method [217, 218].

For semileptonic decays involving a bottom quark, one can use HQET or NRQCD to control the discretization errors of the bottom quark. HQET is also used to constrain the extrapolation of the lattice results obtained in the lower heavy-quark mass region using relativistic lattice fermion actions.

The form factors for the semileptonic decay $B \rightarrow \pi\ell\nu$ (and the similar decay $B_s \rightarrow K\ell\nu$) have been calculated in unquenched lattice QCD by a number of groups [219–228]. These B semileptonic form factors are difficult to calculate at low q^2 , *i.e.* when the mass of the B -meson must be balanced by a large pion momentum, in order to transfer a large momentum to the lepton pair. The low q^2 region has large discretization errors and very large statistical errors, while the high q^2 region is much more accessible to the lattice. For experiment, the opposite is true. To combine lattice and experimental results it has proved helpful to use the z -parameter expansion [143–146]. This provides a theoretically constrained parameterization of the entire q^2 range, and allows one to obtain $|V_{ub}|$ without model dependence [229]. Analyticity and unitarity can be used to obtain further constraints, including extra information on susceptibilities relevant to the form factors in the time-like region [146, 230–233].

The semileptonic decays $B \rightarrow D\ell\nu$ and $B \rightarrow D^*\ell\nu$ (and the similar decays $B_s \rightarrow D_s\ell\nu$ and $B_s \rightarrow D_s^*\ell\nu$) can be used to extract $|V_{cb}|$ once the corresponding form factors are known. The lattice calculation is most precise at zero recoil since the bulk of the systematic error cancels for appropriate ratios between $B \rightarrow D^{(*)}$ and $B \rightarrow B$ or $D^{(*)} \rightarrow D^{(*)}$ [234]. The unquenched calculation of the $B \rightarrow D^{(*)}\ell\nu$ form factor at zero recoil has been performed with various formulations for the heavy quark [235]. Calculations at non-zero recoil have also now been performed to constrain the functional form of the form factor, which can be used to extrapolate the experimental data to the

zero-recoil point or to determine $|V_{cb}|$ directly at the non-zero recoil points [42, 236–241]. The range of q^2 that can be handled for B -meson decays in lattice QCD is growing as more accurate results become available on finer lattices. Comparison of the shape of the form factors between lattice calculations and experiments provides non-trivial cross checks. Semileptonic decays of the Λ_b baryon can also be used to constrain $|V_{cb}|$ and $|V_{ub}|$ using lattice calculations of the relevant form factors [242].

The rare decays $B \rightarrow K\ell^+\ell^-$ involve matrix elements similar to those needed for semileptonic decays, Eq. (17.14), except that the vector current V_μ is replaced by the operators $\bar{s}\gamma^\mu(1-\gamma_5)b$ or $\bar{s}\sigma^{\mu\nu}(1+\gamma_5)b$. Lattice calculations of the corresponding form factors involve similar techniques to those for the semileptonic form factors. The range of q^2 for which lattice calculations can be done is being extended, as above, but here there is an intermediate q^2 region where $c\bar{c}$ resonances are present and this must be avoided. Recent lattice calculations [223, 243, 244] suggest some tension with the experimentally observed decay rate. In these calculations, the long-distance contribution from decay chain $b \rightarrow sc\bar{c} \rightarrow s\ell^+\ell^-$ is ignored. Systematic errors including such long-distance contributions need to be carefully studied before drawing any definite conclusions. A similar study for baryonic decay mode $\Lambda_b \rightarrow \Lambda\ell^+\ell^-$ can be found in Ref. [245].

The results discussed in this section are used in the reviews “The CKM Quark-Mixing Matrix,” “ V_{ud} , V_{us} , the Cabibbo Angle and CKM Unitarity,” and “Semileptonic b -hadron decays, determination of V_{cb} , V_{ub} .”

17.3.4 Strong gauge coupling

As explained in Sec. 17.1.5.1, for a given lattice action, the choice of bare lattice gauge coupling, g_{lat} , determines the lattice spacing a . If one then calculates a as described in Sec. 17.1.5.1, one knows the strong gauge coupling in the bare lattice scheme at the scale $1/a$, $\alpha_{\text{lat}} = g_{\text{lat}}^2/(4\pi)$. This is not, however, useful for comparing to results for α_s obtained from other inputs, such as deep inelastic scattering or jet shape variables. This is because the latter results give α_s in the $\overline{\text{MS}}$ scheme, which is commonly used in such analyses, and the conversion factor between the lattice and $\overline{\text{MS}}$ schemes is known to converge extremely poorly in perturbation theory. Instead, one must use a method which directly determines α_s on the lattice in a scheme closer to $\overline{\text{MS}}$.

Several such methods have been used, all following a similar strategy. One calculates a short-distance quantity K both perturbatively (K^{PT}) and non-perturbatively (K^{NP}) on the lattice, and requires equality: $K^{\text{NP}} = K^{\text{PT}} = \sum_{i=0}^n c_i \alpha_s^i$. Solving this equation one obtains α_s at a scale related to the quantity being used. Often, α_s thus obtained is not defined in the conventional $\overline{\text{MS}}$ scheme, and one has to convert among the different schemes using perturbation theory. Unlike for the bare lattice scheme, the required conversion factors are reasonably convergent. As a final step, one uses the renormalization group to run the resulting coupling to a canonical scale (such as M_Z).

In the work of the HPQCD collaboration [246, 247], the short-distance quantities are Wilson loops of several sizes and their ratios. These quantities are perturbatively calculated through $\mathcal{O}(\alpha_s^3)$ using the V -scheme defined through the heavy quark potential. The coefficients of even higher orders are estimated using the data at various values of a . In addition, this work obtains a result for α_s by matching with α_{lat} in a tadpole-improved scheme that improves convergence.

Another choice of short-distance quantities is to use current-current correlators. Appropriate moments of these correlators are ultraviolet finite, and by matching lattice results to the *continuum* perturbative predictions, one can directly extract the $\overline{\text{MS}}$ coupling [248]. The method can be applied for light meson correlators [249–252] as well as heavy meson correlators [40, 247, 253–256]. Yet another choice of short-distance quantity is the static-quark potential, where the lattice result for the potential is compared to perturbative calculations; this method was used to compute α_s within 2+1 flavor QCD [257–262]. There is also a determination of α_s from a comparison of lattice

data for the ghost-gluon coupling with that of perturbation theory [263, 264].

With a definition of α_s given using the Schrödinger functional, one can non-perturbatively control the evolution of α_s to high-energy scales, such as 100 GeV, where the perturbative expansion converges very well. This method developed by the ALPHA collaboration [106] has been applied to 2+1-flavor QCD in [265–267].

The various lattice methods for calculating α_s have significantly different sources of systematic error. The FLAG review [85] reports an estimate $\alpha_{\overline{\text{MS}}}^{(5)}(M_Z) = 0.1184(8)$, based on Refs. [247, 252, 254, 262, 265, 267–269]. A comparison to other phenomenological determinations can be found in the “Quantum Chromodynamics” review.

17.3.5 Quark masses

Once the quark mass parameters are tuned in the lattice action, the remaining task is to convert them to those of the conventional definition. Since the quarks do not appear as asymptotic states due to confinement, the pole mass of the quark propagator is not a physical quantity. Instead, one defines the quark mass after subtracting the ultra-violet divergences in some particular way. The conventional choice is again the $\overline{\text{MS}}$ scheme at a canonical scale such as 2 or 3 GeV. Ratios such as m_c/m_s and m_b/m_c are also useful as they are free from multiplicative renormalization (in a mass-independent scheme), and can be computed precisely in lattice QCD, with a precision of 0.2% for m_c/m_s [44] and 0.3% for m_b/m_c [77].

As discussed in Sec. 17.1.6.4, one must convert the lattice bare quark mass to that in the $\overline{\text{MS}}$ scheme. Older calculations did so directly using low-order perturbation theory; most recent calculations use an intermediate NPR method (e.g., RI/MOM or RI/SMOM) which is then converted to the $\overline{\text{MS}}$ scheme using three-loop perturbation theory (see, e.g., [41, 190, 270–274]).

Alternatively, one can use a definition based on the Schrödinger functional, which allows one to evolve the quark mass to a high scale non-perturbatively [275, 276], where perturbative matching to the $\overline{\text{MS}}$ scheme can be done accurately.

Other approaches available for heavy quarks are to match current-current correlators at short distances calculated on the lattice to those obtained in continuum perturbation theory in the $\overline{\text{MS}}$ scheme [40, 77, 247, 253–255], or to use HQET mass relations [273, 277]. This has allowed an accurate determination of m_c and m_b [104, 247, 254].

The ratio method for heavy quarks (discussed earlier) can also be used to determine m_b [278].

Results are summarized in the review of “Quark Masses.”

17.3.6 Other physical quantities of interest

In some physics applications, one is interested in the two-point correlation function $\langle O_X(x)O_Y^\dagger(0) \rangle$ for all values of the separation x , not just its asymptotic form for large separations (which is used to determine the hadron spectrum as sketched in Sec. 17.2.2). A topical example, related to the evaluation of the Standard Model contribution to the muon anomalous magnetic moment $g - 2$, is the hadronic vacuum polarization function $\Pi_{\mu\nu}(x) = \langle V_\mu(x)V_\nu(0) \rangle$ and its Fourier transform $\Pi_{\mu\nu}(q^2)$. Since the lattice is in Euclidean space-time, only space-like momenta, $q^2 = -Q^2 < 0$, are accessible. Nevertheless, this quantity is of significant interest. It determines the running of the QED coupling constant α_{QED} , for which non-perturbative effects arise from quark loops. First lattice calculations appeared recently [279, 280]. It is also related by a dispersion relation to the cross section for $e^+e^- \rightarrow \text{hadrons}$, and is needed for a first-principles calculation of the “hadronic vacuum polarization” contribution to the muon anomalous magnetic moment a_μ . Following the pioneering work of Ref. [281], there have been many lattice calculations of this contribution. The status as of March 2020 is summarized in the White Paper of the $g - 2$ Theory Initiative [282]. More recent calculations are those of Refs. [283–285].

Since the relevant scale is set by the muon mass m_μ , this quantity is most sensitive to the

low-energy region $Q^2 \simeq m_\mu^2$ of $\Pi_{\mu\nu}(-Q^2)$, where the long-range contribution of multi-body states become relevant. The lattice calculation is challenging because of this and also because the necessary precision is high (below 0.5%). Many systematic effects must be carefully studied and controlled in order to achieve this precision, including finite volume errors [286], errors from the chiral-continuum extrapolations [285], isospin breaking [287, 288], quark-line disconnected diagrams [288, 289], and QED corrections [288, 290, 291]. One lattice calculation has achieved the required sub-percent precision [283], a level that is comparable to the determination of the HVP contribution using dispersion relations based on e^+e^- scattering data (the “data-driven” approach). The lattice result is in tension with the data-driven approach by 2.1σ . In order to facilitate the comparison among different lattice calculations with controlled systematic errors, the so-called “intermediate window quantity” was introduced [288]. It essentially eliminates short-distance and long-distance contributions to the hadronic vacuum polarization and focuses in the region where the lattice calculation provides the best accuracy. The results from various lattice collaborations [283, 291–293] are in good agreement but disagree with the corresponding data-driven estimate at the level of 3.8σ . This discrepancy between the lattice and data-driven results needs to be understood before drawing any conclusion about new-physics contribution to the muon $g - 2$.

Calculations of the light-by-light scattering contribution to a_μ have been performed. These involve the calculations of four-point correlation functions with various external momenta. Ingenious methods to evaluate the contribution to a_μ have been developed by two groups and the results are in good agreement [294].

There are other quantities for which lattice calculations can make a significant contribution to establishing a quantitative understanding of hadronic processes. One example is the long-distance contribution to the neutral kaon mass splitting, ΔM_K . This also requires the evaluation of a four-point function, constructed from the two-point functions described above by the insertion of two electroweak Hamiltonians [295, 296]. Another example is the long-distance contribution to ϵ_K , which provides a correction to the contribution of the mixing parameter B_K , and has also been computed recently [297]. Rare kaon decays $K \rightarrow \pi\ell^+\ell^-$ and $K \rightarrow \pi\nu\bar{\nu}$ are also important processes for which first lattice studies have appeared [298]. A related process is $\pi^0 \rightarrow e^+e^-$, which has recently been studied on the lattice [299]. Radiative leptonic decays $\pi \rightarrow \ell\nu\gamma^{(*)}$, $K \rightarrow \ell\nu\gamma^{(*)}$, and $D \rightarrow \ell\nu\gamma^{(*)}$ also include two operator insertions, i.e. an electroweak Hamiltonian and an electromagnetic current, and similar techniques developed for the rare decays can be applied. First lattice results have appeared [64, 300]. Finally, we note that similar lattice methods allow the calculation of the γW box contribution to the radiative corrections to semileptonic decays of pions and kaons [301]. The extension to neutron β decay is an important next step, as this promises to reduce the theoretical uncertainty in the extraction of $|V_{ud}|$ from neutron decays. First results have appeared recently [302].

17.3.7 Other applications of lattice QCD

In this review we have concentrated on applications of LQCD that are relevant to the quantities discussed in the Review of Particle Properties. We have not considered at all several other applications that are being actively pursued by simulations. Here we list the major such applications. The reader can consult the aforementioned texts [2–4] for further details, as well as the proceedings of recent lattice conferences [303], and several recent white papers [304].

LQCD can be used, in principle, to simulate QCD at non-zero temperature and density, and in particular to study how confinement and chiral-symmetry breaking are lost as T and μ (the chemical potential) are increased. For example, as T is increased at $\mu = 0$, it is found that, for the physical values of the quark masses, the deconfinement and chiral-symmetry-restoration transitions are smooth crossovers, rather than phase transitions, and that they occur together. This is of

relevance to heavy-ion collisions, the early Universe and neutron-star structure. In practice, finite temperature simulations are computationally tractable and relatively mature, while simulations at finite μ suffer from a “sign problem” and are at a rudimentary stage.

Another topic under active investigation is nucleon structure and inter-nucleon interactions. The simplest nucleon matrix elements are calculable with a precision that is now starting to rival that for some mesonic quantities. Of particular interest are those of the axial current (leading to g_A) and of the scalar density (with $\langle N|\bar{s}s|N\rangle$ needed for dark matter searches), both of which are reviewed by FLAG [85]. Other such matrix elements provide information on the parton distribution functions (PDFs), including their low moments. Recently, methods to directly access PDFs have been developed (see Ref. [305] for a recent review). Also, neutrino-nucleon scattering matrix elements play a crucial role in the estimate of the expected event rate in the current and future neutrino experiments, such as T2K and DUNE. The lattice computation of the matrix elements is similar to those of the meson semi-leptonic decays and the lattice results are reaching the required precision as summarized in [306].

Finally, we note that there is much recent interest in studying QCD-like theories with more fermions, possibly in other representations of the gauge group (see, e.g., [307]). The main interest is to find nearly conformal theories which might be candidates for “walking technicolor” models.

17.4 Outlook

While LQCD calculations have made major strides in the last decade, and are now playing an important role in constraining the Standard Model, there are many calculations that could be done in principle but are not yet mature due to limitations in computational resources. As we move to exascale resources (10^{18} floating point operations per second), the list of mature calculations will grow. Examples that we expect to mature in the next few years are results for B meson and Λ_b baryon form factors covering the full range of q^2 ; results for excited hadrons, including quark-model exotics, at close to physical light-quark masses; results for structure functions and related parton distribution functions; results for a variety of nucleon matrix elements; $K \rightarrow \pi\pi$ amplitudes (allowing a precise prediction of ϵ'/ϵ from the Standard Model); hadronic vacuum polarization contributions to $g_\mu - 2$, the running of α_{EM} and α_s (the status of the first of which was discussed in Sec. 17.3.6); $\pi \rightarrow \gamma\gamma$ and related amplitudes; long-distance contributions to $\bar{K} \leftrightarrow K$ mixing; the light-by-light contribution to $g_\mu - 2$; and determinations of long distance contributions to rare kaon decays such as $K \rightarrow \pi\nu\bar{\nu}$. There will also be steady improvement in the precision attained for the mature quantities discussed above. As already noted, for several of these quantities, attaining the desired precision will require the inclusion of isospin-breaking and electromagnetic effects.

17.5 Acknowledgments

We are grateful to Jack Laiho for his collaboration on previous editions of this review, and to Christine Davies, Takashi Kaneko, and Stefan Meinel for comments and suggestions.
