Abstract

Given the success of neural networks in a variety of applications in engineering, such as speech and image quantization, it is natural to consider its application to similar problems in other domains. A related problem that arises in business is market segmentation for which clustering techniques are used. In this paper, we explore the ability of a specific neural network, namely the Frequency-Sensitive Competitive Learning Algorithm (FSCL), to cluster data for developing strategic marketing decisions. To this end, we investigate the comparative performance of FSCL vis-à-vis the K-means clustering technique. A cluster analysis conducted on brand choice data for the coffee category revealed that the two methodologies resulted in widely differing cluster solutions. In an effort to address the dispute over the appropriate methodology, a comparative performance investigation was undertaken using simulated data with known cluster solutions in a fairly large experimental design to mimic varying data quality to reflect data collection and measurement error. Based on the results of these studies, it is observed that a combination of the two methodologies, wherein the results of the FSCL network are input as seeds to the K-means, seems to provide more managerially insightful segmentation schemes.

1. Introduction

A common research objective across a variety of disciplines is to group items that are similar. This grouping can be of people for identifying market segments; or of cities and regions for selecting test market sites; or of species of plants and animals for classification; or of speech and signals for data compression. The methodologies for such grouping efforts include multivariate analyses and, more recently, neural network techniques.

Management scientists are interested in neural networks particularly for analyzing noisy data, dealing with problems that have no clear cut solutions and their ability to learn. Neural networks have been designed for various purposes, including managerial problems such as handling census data (Openshaw and Wymer, 1991), forecasting (Murtagh, 1991a), time-varying data (Rowher, 1991), bankruptcy prediction (Wilson and Sharda, 1994), the traveling salesman problem (Fort, 1991), and grouping or clustering (Ahalt et al., 1990; Gath and Geva, 1988; Krishnamurthy et al., 1990; Osipenko, 1988).

* Corresponding author.
However for these newer technologies, such as neural networks, to become accepted in practice they should demonstrate at least parity if not superiority over existing techniques. To this end, in this paper we analyze the capabilities of a specific neural network implementation against a more traditional technique, namely K-means, for the general problem of clustering.

Although several networks have been proposed, little comparison with traditional techniques is available. Further, different applications of the same basic technique may produce different results leading to a lack of stability in the cluster solutions as illustrated in Section 3. The researcher must determine which data reduction method to use for his/her purposes. Which method is best for the data characteristics, the sample size, the amount of data reduction needed? Some of the more common techniques, such as factor analysis and clustering, have extensive research bases behind them to suggest where problems may arise and which methods might be best for which data characteristics and purposes (e.g., Bezdek and Hathaway, 1990; Milligan, 1980; Milligan and Cooper, 1985; Cooper and Milligan, 1988; Dubes, 1987).

The recent interest in neural network analysis has resulted in numerous techniques suggested for many different applications (e.g., Fort, 1991; Hecht-Nielsen, 1990; Kohonen, 1982a,b,1989). This relatively new methodological area has had little of the rigorous testing of these newly suggested methods to help the researcher answer comprehensively the questions posed in the preceding paragraph. A small literature, however, is beginning to develop (e.g., Balakrishnan et al., 1992, 1994; Bezdek, 1991; Naylor and Li, 1988).

This paper reports on the performance of one kind of neural network, the Frequency-Sensitive Competitive Learning (FSCL) network developed by Krishnamurthy et al. (1990) for vector quantization. This method is compared with K-means non-hierarchical clustering. Both of these methods attempt to achieve the same objective, namely, associating a set of objects with a corresponding representative object. In vector quantization, the goal is to classify vectors into classes. In engineering applications these vectors represent input from speech or images. In management applications, such as market segmentation, data are collected in the form of attribute’s values and clustering techniques are used to classify each data point. In either case, the goal is to classify the input into one of the pre-specified number of output groups.

One of the problems in applying these techniques directly to real data for market segmentation is that the results obtained from the two techniques do not typically match. Since there is no absolute criterion to unequivocally say the results of one technique are right and the other wrong it becomes incumbent on the researcher to test these techniques using simulated data whose properties are known (Milligan and Cooper, 1987). This paper, therefore, examines both simulated data and brand choice probabilities data to compare the FSCL neural network with the K-means algorithm.

The remainder of the paper is organized into a brief explanation of the two approaches, the methodology for the study, the results of the study, limitations of the study, and conclusions and future research directions.

2. Neural networks

A neural network consists of two basic components: processing elements (or nodes) and their interconnections. The processing element receives a number of input signals and then generates a single output signal which is then “sent” to one or more processing elements via the interconnections. How the nodes are connected to each other between the various layers constitutes the system’s knowledge and determines how the neural network will respond to any arbitrary input. A connection between two nodes could have positive or negative weights. The weight $w_{ij}$ is positive if node $j$ excites node $i$ and negative if $j$ inhibits $i$. The strength of the connection is given by the absolute value of the weight $w_{ij}$. The pattern of connectivity can be represented by a weight matrix $W$ in which $w_{ij}$ represents the strength and sense (i.e., excitatory or inhibitory) of the connection between $j$ and $i$. During the learning process these weights are modified based on the learning algorithm used and the desired output (supervised learning) for a given input. Since several sources discuss the concept of neural networks in detail (see for example, Rumelhart et al., 1987; Nelson and
Illingworth, 1991; Hecht-Nielsen, 1990), here we will only discuss the specific approach we have used.

2.1. The FSCL network

Krishnamurthy et al. (1990) and Ahalt et al. (1990) report on a revised method of vector quantization using frequency sensitive competitive learning (FSCL). Vector quantization is described as "a statistical method of encoding data for transmission to a receiver" (Krishnamurthy et al., 1990). Neural networks are suggested as particularly suited to this task since they are adaptive in two senses. First, each new training vector can modify the codebook vectors so there is on-line learning. This may be needed when the source statistics change over time, for example, when communication channels are changed. Second, neural networks can process one vector of data at a time instead of requiring the entire training set to be processed at once in a batch mode, as in the approach by Linde et al. (1980). The latter is particularly computationally intensive (Krishnamurthy et al., 1990).

The frequency sensitive competitive learning algorithm works as follows. Information or voices can be represented as a vector \( x \) consisting of \( k \) dimensions. Usually, \( k \) dimensions are too large for transmission over current lines or fiber optics. Therefore, the \( k \) dimensions must be reduced to a smaller number for transmission.

To compress the data or voice for transmission, there needs to be a system for encoding the data before transmission and then decoding it at the receiving location. A codebook is used for this purpose. The codebook \( C \) consists of \( M \) codewords \( c_i \), each of \( k \) dimensions. One of the \( M \) codewords is used to represent the \( k \)-dimensional vector \( x \). This is basically a data reduction approach. The codebook is developed using a large set of training data.

When a vector is to be encoded, it is matched with the closest codeword by calculating the distortion \( d(x, c_i) \), \( i = 1, \ldots, M \) between the vector and each codeword. If the \( j \)th codeword is the closest, the vector is then encoded as codeword \( c_j \). Upon receipt of the signal, the receiver decodes using the appropriate codeword.

The basic neural network will have \( M \) neural units, each with an associated weight vector that is the \( i \)th codeword, i.e., \( w_i = c_i \). All \( k \) dimensions of the input vector \( x \) are fed in parallel to the neural network. Distortions \( d(x, w_i) \) are calculated between the input vector and each of the \( M \) units. The distortions may be measured using some distance measure, the Euclidean distance being a common approach for clustering techniques. The unit with the minimum distortion 'wins' and the input vector is assigned to the codeword \( c_i \).

In this process, a few codewords may account for a disproportionate share of the input vectors. Grossberg (1976) and Hecht-Nielsen (1988) suggest means of minimizing the winner-take-all problem. Lippmann (1987) and Winters and Rose (1989) indicate means of finding the winner. Competitive learning algorithms adjust the weight vectors of neural units that win too frequently, or are in the neighborhood of the winner in the case of the Kohonen self-organizing map (Kohonen, 1989). Competitive learning is useful if a criterion of the effort is to maximize entropy, that is, to have codewords chosen with relatively equal frequency.

The Frequency-Sensitive Competitive Learning (FSCL) Training Algorithm counts the number of times, \( u_i \), a particular unit wins and increases the distortion measure using the non-decreasing 'fairness' function \( F(u_i) \). The fairness function initially favors uniform codeword usage but minimizes distortion as training progresses. The algorithm is an implementation of the Grossberg conscience principle and works as follows (Krishnamurthy et al., 1990):

1. Consider an input vector \( x \).
2. Find the distortion \( D_i = F(u_i)d(x, w_i) \) for all output units.
3. Select the output unit \( i^* \) with the smallest distortion and label it as the winning unit and increment \( u_{i^*} \).
4. Adjust the selected weight vector \( w_{i^*}(n + 1) = w_{i^*}(n) + \epsilon(n)[x(n) - w_{i^*}(n)] \) where \( n \) is the training time and \( 0 < \epsilon(n) < 1 \).
5. Repeat steps 1–4 for all training vectors.

2.2. K-means clustering

Clustering algorithms are a class of data reduction techniques. Hierarchical clustering algorithms start with \( n \) clusters, where \( n \) is the number of observations, such as people, each having information on \( k \)
dimensions, such as demographic data. The distance between observations is calculated in $k$-dimensional space. The two closest points are merged into a cluster. This process continues until all observations are in one cluster. One then has to determine the number of clusters using a decision rule (Milligan and Cooper, 1985).

In non-hierarchical clustering, the researcher specifies the number of clusters in the data set a priori. Since this approach matches the vector quantization problem, a non-hierarchical method is used here for comparison. The $K$-means procedure, as used by FASTCLUS in SAS (SAS, 1990), selects $M$ random points from the data set. These are used as cluster seeds and all other points are assigned to the nearest cluster seed. Successive iterations involve replacing the current cluster seed by the cluster mean and then reassigning all points to the nearest new cluster seed. The process continues until there is no change in cluster means from the previous iteration or the difference is very small.

3. An application of the FSCL network and $K$-means methodology

The actual data employed in this study represent the brand switching probabilities on 18 different coffee brands derived from scanner data. The data collection procedure and method of constructing these switching probabilities are described in Bucklin and Srinivasan (1991). The input to the $K$-means clustering algorithm and FSCL network was an average probability switching vector (18-dimensional) at the sub-household level. There were a total of 207 sub-households which were to be clustered into six distinct segments as recommended by Bucklin and Srinivasan (1991). Each of these 207 objects to be grouped was represented by a vector specifying choice probabilities for 18 brands of coffee.

The data set comprising $207 \times 18$ choice probabilities was then clustered using the FSCL network as well as the $K$-means algorithm to generate a six-segment solution. In the study, the $K$-means procedure for non-hierarchical clustering was performed with iterations. In this case, the algorithm needed 11 iterations to converge using the default values and stopping rule.

The resulting cluster solutions that were generated by these alternate methods were then compared for similarity on the criteria of (1) segment size, (2) segment means, and (3) their managerial interpretation. In Table 1, we show the comparative results of the six-cluster solutions produced by the $K$-means procedure (FASTCLUS) and the FSCL network (Ahlal et al., 1990). Even a cursory glance at this table indicates that the FSCL network results are not similar to those produced by $K$-means. Both methods differed in something as fundamental as the size of the individual clusters. For instance, the largest segment had 67 members using $K$-means while the largest FSCL cluster had 42 members. Interestingly, the FSCL procedure generated six clusters that, consistent with our prior expectations, were more or less of equal size, varying only from the largest with 42 to the smallest with 31 members. On the other hand, the $K$-means procedure generated widely varying sized clusters. Naturally enough, the two procedures did not produce cluster means that were identical.

Given that clusters differ by method, the next issue is their managerial interpretability. For comparative purposes and to be consistent with prior analysis of Bucklin and Srinivasan (1991), we use a mean of 0.08 as the 'critical cut-off' value in 'assigning' brands to a particular segment's choice activity. This implies that we can characterize the clusters generated by the two methods as follows. In the case of $K$-means (with iterations): cluster 1 is a ground caffeinated segment (excluding the store private label brand); cluster 2 is an instant caffeinated segment; cluster 3 is a decaffeinated segment; and, cluster 4 is Folgers ground caffeinated segment. Clusters 5 and 6 are primarily the store private label ground caffeinated segment and the Maxwell House instant caffeinated segment, respectively. The FSCL network generated segments can be characterized as follows: cluster 1 is the ground caffeinated segment emphasizing Maxwell House and Master Blend; cluster 2 is Sanka and ground decaffeinated segment; cluster 3 is an instant caffeinated (emphasizing Maxwell House) and store brand ground caffeinated segment; cluster 4 is Nescafe instant caffeinated and instant decaffeinated segment; cluster 5 is a Folgers segment; and cluster 6 is primarily Maxwell house ground caffeinated segment.

As we can see, the managerial interpretation of

the two sets of segments is not the same. This raises an interesting question about which segmentation scheme should be adopted in the development of marketing strategies. To answer such a question requires studying the comparative performance of the two approaches to cases wherein the ‘true’ cluster solutions are known. To this end, the next stage of the research, then focuses on studying the two approaches on simulated data with known cluster solutions representing different qualities of data.

4. Methodology

Several factors can affect the quality of cluster recovery, such as the number of clusters in the data, the number of dimensions used to describe the data, and the level of error in the data (Milligan, 1980). This study consists of a full factorial experimental design crossing the number of clusters with the number of dimensions (attributes) with levels of error. The result is a $4 \times 3 \times 3$ design with three replications per cell, for a total of 108 data sets. This is a common approach to evaluating clustering methods (Milligan, 1980; Milligan and Cooper, 1985, 1987). Each data set is generated using the procedure of Milligan (1985) procedure and contains 50 points. The FSCL network and the $K$-means algorithms each clustered all 108 data sets.

The number of true clusters in each data set was 2, 3, 4, or 5 with a roughly equal distribution of points in each cluster. The number of measures (i.e., attributes) used to characterize each data set was varied so that all points in a data set were described by a 4-, 6-, or 8-dimensional space. The three levels of error were no error, low error, or high error. The no error level would be similar to a noiseless transmission of data or data obtained when there is no data collection and measurement error.

The simulation data were generated as truncated, multivariate normal distributions in Euclidean space. The data sets were created to have reasonably distinct and separate clusters as defined by internal cohesion and external isolation (Cormack, 1971). Internal cohesion in these data sets require all data points to be within the boundaries of the cluster on all dimensions. Boundaries were three standard deviations across for all dimensions. External isolation was operationalized by having the first dimension be non-overlapping. The distance between clusters was $f(S_1 + S_2)$, where $f$ is the separation factor and $S_1$ and $S_2$ are the standard deviations of cluster 1 and 2, respectively, on the first dimension (see Milligan, 1985). The value of $f$ was randomly selected from a uniform distribution bounded by 0.25 and 0.75. Other dimensions were permitted to overlap. Thus, cluster separation is guaranteed on the first dimension only in the non-error condition.

The data point coordinates were error-perturbed to distort the true distances between points to achieve low and high error. This simulates noise in the data which can occur with data collection or measurement error. The low error condition still did not permit overlap on the first dimension but the separation was very small. The high error condition did have cluster overlap on the first dimension and possibly on the other dimensions. New interpoint distances were calculated using $[\Sigma(A_{ij} - A_{ik} - \delta e_{ijk})^2]^{1/2}$, where $A_{ij}$ and $A_{ik}$ are the original coordinate values for observation $j$ and $k$ on dimension $i$. The error term is generated from a univariate normal distribution with a mean of zero and a standard deviation determined by taking the average of the standard deviations on dimension $i$ for the two clusters containing points $j$ and $k$. The multiplication factor, $\delta$, had values of 1 or 2, which determined the low and high error levels, respectively (Milligan, 1985).

The FSCL network used the fairness function $F(u_t) = u_t \beta e^{-1/T}$ where $\beta$ and $T$ are constants and $t$ is the training iteration number. The current implementation uses a $\beta$ value of 0.06 and $1/T$ value of 0.00005. The learning rate used was $\epsilon(n) = 0.06 e^{-0.05(n-1)}$.

5. Results on simulated data

The results of the $K$-means clustering and FSCL network techniques were compared on overall cluster recovery and sensitivity to cluster characteristics. The percent of the 50 observations misclassified by the different techniques indicated cluster recovery. Analyses of variance (ANOVAs) using the general linear models procedure (GLM) available in the current edition of SAS (1990) tested hypotheses about the effects of the data characteristics on the
clustering results. Results of these analyses are presented in Tables 2 and 3.

K-means recovered the correct cluster structure of each error-free data set with no more than five iterative re-computations of the cluster seeds. The majority of the low and high error data sets were also correctly classified by the FASTCLUS procedure. Only a few of the data sets were poorly classified which increased the average number of misclassifications across all data sets.

**Hypothesis 1.** The percentage of misclassifications does not differ across error levels.

For both K-means and FSCL the main effect for the level of error in the data was significant. For the K-means case the error level was significant at the 0.01 level \((N = 108, p < 0.001)\). The mean misclassification of observations increased from 0.0% to 0.22% to 3.78% for the no error, low error, and high error data sets, respectively (Table 3).

The FSCL network results are similar to the K-means case. However, the percentage of misclassifications for all three levels was higher for the FSCL networks (see Fig. 1). Recovery deteriorated as additional error was introduced to the data. The error levels ranged from 7.28% for the no error condition, to 13.78% for the high error condition. The low error condition was close to the no error results at 6.5%.

**Hypothesis 2.** The percentage of misclassifications does not differ across the number of clusters in the data set.

Since the data always consisted of 50 points, as the number of clusters increase there are fewer points for the algorithms to consider in each cluster. This hypothesis was confirmed for the K-means case, however for FSCL the hypothesis was rejected \((p = 0.005)\). In the case of the FSCL network, as the number of clusters increased, cluster recovery deteriorated, reaching 15.26% for five clusters. The best recovery was for two clusters with 4.96% of the data points misclassified. The two and three cluster (6.07%) misclassification rates were much lower than the four (10.44%) and five (15.26%) rates (see Fig. 2). Closer examination of the results suggests that there is a tendency to overcluster, that is, to have two
true clusters merged into one cluster. When this happens information is lost by not separating the true clusters.

**Hypothesis 3.** The percentage of misclassifications does not differ across the number of attributes of each object.

Previous clustering research results indicate that more, relevant attributes should lead to better recovery (e.g., Milligan, 1980). However, in the case of the K-means approach there was no significant effect (see Table 2) on the percentage of misclassifications, although the percent misclassified with eight attributes was the lowest amongst three levels (see Table 3).

In the case of the FSCL network, recovery improved as the number of attributes increased from four to eight. Half as many points were misclassified (6.28%) when eight dimensions were used as when four dimensions were used (12.83%) (see Fig. 3). This pattern is consistent with that reported by Krishnamurthy et al. (1990) for up to 128 dimensions in the case of an engineering application.

6. Brand choice data revisited

Given the above results of the studies on both simulated and actual data, we now revisit the brand switching data on the 18 different brands of coffee reported in Section 3. The major conclusions of the above two studies is that each method seems to have something to recommend. Specifically, based on the above results, we find that, the use of K-means proved to be more accurate in the classification of synthetic data. However, the use of the FSCL network with its ‘conscience mechanism’ had less variation in the cluster sizes on the larger real data.

This provoked the natural extension of whether the combination of the two disparate methods could lead to even more managerially useful results than either alone. Although the K-means approach provides a better ‘hit rate’ on synthetic data, it is well-known to be prone to the biases involved in the selection of initial cluster seeds (Milligan, 1980). This problem of seed selection was, however, mitigated in the case of the synthetic data by knowing a priori the correct number of clusters, and by having relatively errorfree information. Though the results of this experiment do suggest that its internal validity is relatively higher, these simulation conditions that resulted in the superior performance of K-means may be less likely to hold in actual applications.

Since, as noted earlier, seed selection is an important issue with K-means, we decided to combine the two approaches by employing the FSCL network to

---

1 We would like to thank the reviewers of this journal for their insightful comments on this.
assist in providing the initial seeds. We use the FSCL network results as the seeds to the $K$-means method, the approach that we ‘trust’ more for the final cluster solution. The resulting solution should be intriguing because we now have the opportunity to assess how the $K$-means results change with the new seeds. If the $K$-means method is particularly robust, then even with the different starting point the results may turn out to be identical to the original $K$-means. Alternatively, given the new starting point, the results could be similar to the FSCL results or somewhere in between the original FSCL and $K$-means results. Hence, we now have the opportunity to assess the quality of the resulting solution in terms of ease of interpretation, face validity, and disparity in the obtained cluster sizes when the seeds from FSCL are employed.

In the study, the $K$-means procedure for non-hierarchical clustering was performed with iterations using as the input seeds (reported in Table 1) the centroids of the cluster solution provided by the FSCL network. In this case, the $K$-means algorithm needed 15 iterations to converge using the traditional default values stopping rule 2 (see Table 4).

Interestingly, the resulting solution provided clusters of more equal sizes than the $K$-means method by itself. The variation of cluster sizes ranged from a high of 49 to a low of 19 3. Given that these cluster sizes are managerially more useful, the next issue is their managerial interpretability. We can characterize the clusters generated by the combination of the two methods as follows: cluster 1 is the segment Maxwell House and Master Blend ground caffeinated; cluster 2 is the ground decaffeinated segment; cluster 3 is the instant caffeinated segment; cluster 4 is the instant decaffeinated segment; cluster 5 is the Folgers ground caffeinated segment; and cluster 6 is the ground caffeinated segment emphasizing Maxwell House.

As should be fairly clear from the above cluster solution, the resulting segments are much ‘cleaner’, and have better managerial interpretability than either of the methods individually as reported in Table 1. In particular, the combined approach seems to have generated clusters with greater precision. For instance, even though we started with the seeds using the FSCL network, the new cluster 5 with 19 households and 0.64 choice probability for Folgers’ ground caffeinated (GC-F) is more meaningful than the one obtained by FSCL alone which had 32 members but grouped together more households with greater purchase variations to lower the GC-F choice probability to 0.41. Similarly, the new cluster 1 has fewer (35) members who on aggregate have a much higher purchase probability (0.45) for the ‘Master Blend-ground caffeinated’ when compared with 67 members with 0.30 choice probability for the $K$-means stand alone approach. Again, the new cluster 2 identifies more precisely the members of the Ground Decaffeinated segment, i.e., those having greater purchase probabilities, than either of the other two methods by themselves. The higher ‘face validity’ of the results obtained, and the fewer anomalies present, seems to imply that the combination of conventional statistical techniques along with the newer machine learning algorithms may have much to offer and might be the direction to take in the future.

7. Discussion and conclusions

While the procedure for generating data sets in the study reported here has been used for clustering research comparisons, it has only been used once for neural networks (Balakrishnan et al., 1994). As such, some limitations relating to the study are noted. First, the number of data points may be considered relatively small when compared to those commonly used for neural networks. Second, conducting the analysis on error-free data and knowing the correct number of clusters in the data may have favorably biased the results as the most serious problem in the $K$-means approach is the selection of initial cluster seeds (see Milligan, 1980). Using the correct number of clusters and error-free data significantly reduced the problem of selecting the seeds. Analyses conducted on data with skewed distributions or other forms of error may result in a lower recovery rate.

Despite these limitations, the $K$-means algorithm performed well. Although the FSCL network chosen for this study did not perform well, several contributing factors should be considered that would provide the basis for future research in the area. It should first be noted that the unsupervised learning approach used in the FSCL network makes it a natural starting point to explore for use in clustering. Kangas et al. (1990) suggest that for pattern recognition or other decision processes it is possible to significantly improve recognition accuracy by ‘fine tuning’ with additional information. More importantly, the information needed to minimize misclassification involves employing multiple codebook (i.e., weight) vectors to represent each cluster. These multiple vectors, they suggest, are the vectors defining the boundaries of the clusters rather than the typical centroids. Unfortunately, in the context of applied research, the very boundaries of the clusters are typically not known and have to be determined.

Another problem is the choice of the parameters for the neural network. How does one choose the appropriate network parameters for a data set? There is really no clear cut answer to this problem in the unsupervised framework. Here, since the cluster solutions were known, the parameters were set based on an initial study of the hit rate on a small sub-set of the data sets. However, since this not feasible in real data sets, another approach might be to choose parameters that generate more or less equal clusters.

Cluster recovery for the FSCL network improved as more relevant attributes were added. This is consistent with previous clustering results and suggests that the more, useful information available for the FSCL network, the better the recovery. By itself, based on the simulation data results, the FSCL method should be used with considerable caution for clustering purposes. Of concern is the significant sensitivity of the FSCL network to increases in error level and to increases in the numbers of clusters. If the dimension of $k$ for the codebook is very large, there may be a better chance to select the correct assignment of data points to clusters.

Another aspect that has been investigated in this research is the combining of the results of the neural network methodology with the $K$-means approach. This combination for the market data considered here has resulted in better solutions than when either technique was used by itself. Future research should be conducted to extensively study the implications of such integration.

Future research should also investigate different data characteristics, such as kinds of error perturbations including skewed distributions and the influence of outliers in the data. For now, users of the FSCL network should be cautious about using it for clustering small data sets. It appears to work better for larger numbers of training data, e.g., 14000 vectors (Krishnamurthy et al., 1990) Additionally, the FSCL algorithm has been shown to perform better than the Kohonen self-organizing map (Ahalt et al., 1990), however, the $K$-means algorithm out performed the FSCL algorithm in this study.

Acknowledgements

The authors acknowledge Profs. Stan Ahalt and Ashok Krishnamurthy of the Electrical Engineering Department at Ohio State for their assistance on this project. We thank Randy Bucklin and Seenu Srinivasan for making available the Coffee data. We also thank Pete Nye, and the anonymous reviewers of this journal for their constructive suggestions.
