Introduction

- Genetic association studies are widely used for the identification of genes that influence complex traits.
- To date, hundreds of thousands of individuals have been included in genome-wide association studies (GWAS) for the mapping of both dichotomous and quantitative traits.
- Large-scale genomic studies often have high-dimensional data consisting of
  - Tens of thousands of individuals
  - Genotypes data on a million (or more!) SNPs for all individuals in the study
  - Phenotype or Trait values of interest such as Height, BMI, HDL cholesterol, blood pressure, diabetes, etc.
Introduction

- The vast majority of these studies have been conducted in populations of European ancestry.
- Non-European populations have largely been underrepresented in genetic studies, despite often bearing a disproportionately high burden for some diseases.
- Recent genetic studies have investigated more diverse populations.
Case-Control Association Testing

- The observations in association studies can be confounded by population structure
  - **Population structure**: the presence of subgroups in the population with ancestry differences
- Neglecting or not accounting for ancestry differences among sample individuals can lead to **false positive** or **spurious associations**!
- This is a serious concern for all genetic association studies.
In statistics, a **confounding variable** is an extraneous variable in a statistical model that correlates with both the dependent variable and the independent variable.
Ethnic groups (and subgroups) often share distinct dietary habits and other lifestyle characteristics that leads to many traits of interest being correlated with ancestry and/or ethnicity.
Spurious Association

- Case/Control association test
  - Comparison of allele frequency between cases and controls.
- Consider a sample from 2 populations:
  - Red population overrepresented among cases in the sample.
  - Genetic markers that are not influencing the disease but with significant differences in allele frequencies between the populations
    $\implies$ spurious association between disease and genetic marker
Spurious Association

- Quantitative trait association test
  - Test for association between genotype and trait value
- Consider sampling from 2 populations:
  - Blue population has higher trait values.
  - Different allele frequency in each population
  - Spurious association between trait and genetic marker if one population is overrepresented in the sample
Suppose the data for the genetic association study include genotype and phenotype on a sample of $n$ individuals.

Let $\mathbf{Y} = (Y_1, \ldots, Y_n)^T$ denote the $n \times 1$ vector of phenotype data, where $Y_i$ is the quantitative trait value for the $i$th individual.

Consider testing SNP $s$ in a genome-screen for association with the phenotype, where $\mathbf{G}_s = (G_1^s, \ldots, G_n^s)^T$ is $n \times 1$ vector of the genotypes, where $G_i^s = 0, 1, \text{ or } 2$, according to whether individual $i$ has, respectively, 0, 1 or 2 copies of the reference allele at SNP $s$. 

Genotype and Phenotype Data
Genomic Control

- Devlin and Roeder (1999) proposed correcting for substructure via a method called "genomic control."
- For each marker $s$, the Armitage trend statistic is calculated

$$A_{rs} = Nr^2_{G_sY}$$

where $r^2_{G_sY}$ is the squared correlation between the genotype variable $G_s$ for marker $s$ and the phenotype variable $Y$.
- If there is no population structure, the distribution of $A_{rs}$ will approximately follow a $\chi^2$ distribution with 1 degree of freedom.
- If there is population structure, the statistic will deviate from a $\chi^1$ distribution due to an inflated variance.
Genomic Control

- Use $\lambda = \frac{\text{median}(A_{r1}, ..., A_{rs}, ..., A_{rM})}{.456}$ as a correction factor for cryptic structure, where .456 is the median of a $\chi_1^2$ distribution.

- The uniform inflation factor $\lambda$ is then applied to the Armitage trend statistic values

$$\tilde{A}_{rs} = \frac{A_{rs}}{\lambda}$$

- $\tilde{A}_{rs}$ will approximately follow a $\chi^2$ distribution with 1 degree of freedom.
Correcting for Population Structure with PCA

- Principal Components Analysis (PCA) is the most widely used approach for identifying and adjusting for ancestry difference among sample individuals.

- Consider the genetic relationship matrix $\hat{\Psi}$ discussed in the previous lecture with components $\hat{\psi}_{ij}$:

$$\hat{\psi}_{ij} = \frac{1}{M} \sum_{s=1}^{M} \frac{(X_{is} - 2\hat{p}_s)(X_{js} - 2\hat{p}_s)}{\hat{p}_s(1 - \hat{p}_s)}$$

where $\hat{p}_s$ is an allele frequency estimate for the type 1 allele at marker $s$. 

Correcting for Population Structure with PCA

- Price et al. (2006) proposed corrected for structure in genetic association studies by applying PCA to $\hat{\Psi}$.
- They developed a method called EIGENSTRAT for association testing in structured populations where the top principal components (highest eigenvalues)
- EIGENSTRAT essentially uses the top principal components from the PCA as covariates in a multi-linear regression model to correct for sample structure.

$$Y = \beta_0 + \beta_1 X + \beta_2 PC_1 + \beta_3 PC_2 + \beta_4 PC_3 + \cdots + \epsilon$$

- $H_0 : \beta_1 = 0$ vs. $H_a : \beta_1 \neq 0$
The EIGENSTRAT methods was developed for unrelated samples with population structure.

Methods may not be valid in samples with related individuals (known and/or unknown).

Many genetic studies have samples with related individuals.
Incomplete Genealogy

- Cryptic and/or misspecified relatedness among the sample individuals can also lead to spurious association in genetic association studies
Incomplete Genealogy
Association Testing in samples with Population Structure and Relatedness

- Linear mixed models (LMMs) have been demonstrated to be a flexible approach for association testing in structured samples. Consider the following model:

\[ Y = W\beta + G_s\gamma + g + \epsilon \]

- **Fixed effects:**
  - \( W \) is an \( n \times (w + 1) \) matrix of covariates that includes an intercept
  - \( \beta \) is the \( (w + 1) \times 1 \) vector of covariate effects, including intercept
  - \( \gamma \) is the (scalar) association parameter of interest, measuring the effect of genotype on phenotype
Linear Mixed Models for Genetic Association

\[ Y = W\beta + G_s\gamma + g + \epsilon \]

- **Random effects:**
  - \( g \) is a length \( n \) random vector of polygenic effects with 
    \[ g \sim N(0, \sigma_g^2 \Psi) \]
  - \( \sigma_g^2 \) represents additive genetic variance and \( \Psi \) is a matrix of 
    pairwise measures of genetic relatedness
  - \( \epsilon \) is a random vector of length \( n \) with \( \epsilon \sim N(0, \sigma_e^2 I) \)
  - \( \sigma_e^2 \) represents non-genetic variance due to non-genetic effects 
    assumed to be acting independently on individuals
The matrix $\Psi$ will be generally be unknown when there is population structure (ancestry differences) and/or cryptic relatedness among sample individuals.

Kang et al. [Nat Genet, 2010] proposed the EMMAX linear mixed model association method that is based on an empirical genetic relatedness matrix (GRM) $\hat{\Psi}$ calculated using SNPs from across the genome. The $(i, j)th$ entry of the matrix is estimated by

$$
\hat{\Psi}_{ij} = \frac{1}{S} \sum_{s=1}^{S} \frac{(G_i^s - 2\hat{p}_s)(G_j^s - 2\hat{p}_s)}{2\hat{p}_s(1 - \hat{p}_s)}
$$

where $\hat{p}_s$ is the sample average allele frequency. $S$ will generally need to be quite large, e.g., larger than 100,000, to capture fine-scale structure.
EMMAX

- For genetic association testing, the EMMAX mixed-model approach first considers the following model without including any of the SNPs as fixed effects:

\[ Y = \mathbf{W}_f \beta + \mathbf{g} + \epsilon \]  

(1)

- The variance components, \( \sigma_g^2 \) and \( \sigma_e^2 \), are then estimated using either a maximum likelihood or restricted maximum likelihood (REML), with \( \text{Cov}(Y) \) set to \( \sigma_g^2 \hat{\Sigma} + \sigma_e^2 \mathbf{I} \) in the likelihood with fixed \( \hat{\Sigma} \).
EMMAX

- Association testing of SNP $s$ and phenotype is then based on the model

\[ Y = W\beta + G^s\gamma + g + \epsilon \]

- The EMMAX association statistic is the score statistic for testing the null hypothesis of $\gamma = 0$ using a generalized regression with $\text{Var}(Y) = \Sigma$ evaluated at $\hat{\Sigma} = \hat{\sigma}_g^2 \hat{\Psi} + \hat{\sigma}_e^2 I$

- EMMAX calculates $\hat{\sigma}_g^2$ and $\hat{\sigma}_e^2$ only once from model (1) to reduce computational burden.
Zhou and Stephens [2012, Nat Genet] developed a computationally efficient mixed-model approach named GEMMA.

GEMMA is very similar to EMMAX and is essentially based on the same linear mixed-model as EMMAX:

\[ Y = W\beta + G^s\gamma + g + \epsilon \]

However, the GEMMA method is an "exact" method that obtains maximum likelihood estimates of variance components \( \hat{\sigma}_g^2 \) and \( \hat{\sigma}_e^2 \) for each SNP being tested for association.

Zhou and Stephens (2012) "Genome-wide efficient mixed-model analysis for association studies" Nature Genetics 44
Other LMM approaches for Quantitative Traits

- A number of similar linear mixed-effects methods have recently been proposed for association testing with quantitative traits when there is cryptic structure: Zhang et al. [2010, Nat Genet], Lippert et al. [2011, Nat Methods], Zhou & Stephens [2012, Nat Genet], and Svishcheva [2012, Nat Genet], and others.
GMMAT: Logistic Mixed Model for Dichotomous Phenotypes

Control for Population Structure and Relatedness for Binary Traits in Genetic Association Studies via Logistic Mixed Models

Han Chen,1,8 Chaolong Wang,1,2,8 Matthew P. Conomos,3 Adrienne M. Stilp,3 Zilin Li,1,4 Tamar Sofer,3 Adam A. Szpiro,3 Wei Chen,5 John M. Brehm,5 Juan C. Celedón,5 Susan Redline,6 George J. Papanicolaou,7 Timothy A. Thornton,3 Cathy C. Laurie,3 Kenneth Rice,3 and Xihong Lin1,*

The GMMAT can be used to conduct a logistic mixed model regression analysis of binary traits for GWAS with population structure and relatedness.
GMMAT: Logistic Mixed Model for Dichotomous Phenotypes

- Let $\pi_i$ be the probability that individual $i$ is affected with the disease. The GMMAT logistic mixed model is:

$$
\log \left( \frac{\pi_i}{1 - \pi_i} \right| W, G_s) = W\beta + G_s\gamma + g
$$

- **Random effect:**
  - $g$ is a length $n$ random vector of polygenic effects with
    $$
g \sim N(0, \tau_g \Psi)
    $$
  - $\tau_g$ is the variance component parameter for polygenic effects
  - GMMAT tests the association parameter $\gamma$ under the null hypothesis of $H_0 : \gamma = 0$. 
ROADTRIPS for Dichotomous Phenotypes

- Similar to LMMs, the ROADTRIPS approach of Thornton and McPeek (2010) also incorporates an empirical covariance matrix $\hat{\Psi}$.

- ROADTRIPS was developed for valid association testing in case-control samples with partially or completely unknown population and pedigree structure.

- ROADTRIPS extensions, to samples with structure, have been developed for a number of association tests including Pearson $\chi^2$ test and the Armitage trend test.
