Goals: familiarize you with basics of using a Kalman Filter to estimate and control the state of a flying robot in simulation.

Required Reading:

- Optimization-Based Control by Richard M. Murray, Chapter 6: Kalman Filtering. See also Chapter 5 for a review of random variables.

Optional reading:

- Koenderink1987, “Facts on Optic Flow,” Biological Cybernetics 1987 (on the course web page) presents a derivation of optic flow (slightly different than in class).

1. State estimation using a Kalman Filter

The Kalman Filter can estimate the state of the system using sensor readings (typically fewer in number than the size of the state), and a model of the dynamics. Given a dynamical system excited by zero-mean process noise \( d \) and measurement noise \( n \),

\[
\dot{q} = \dot{A}q + Bu + Gd \\
y = Cq + n
\]

with covariances \( E\{dd^T\} = Q_N = Q_N^T \geq 0 \), \( E\{nn^T\} = R_N = R_N^T > 0 \), a Kalman Filter consists of an observer gain matrix \( L \) such that the “state estimation dynamics”

\[
\dot{\hat{q}} = \dot{A}\hat{q} + Bu + L(y - C\hat{q})
\]

produces a state estimate \( \hat{q} \) that minimizes the expected squared error using the sensor measurements \( y \). The quantity \( y - C\hat{q} \) represents the error between the current estimate and the sensor readings, which the filter uses to correct its estimate of the full state. Only if the system is observable can the full state be estimated.

In this problem you will write a Kalman Filter to estimate (but not control) the state of nonlinear downward-hanging pendulum dynamics using a noisy measurement of the angle of the pendulum. The dynamics of the pendulum are given by

\[
ml^2\ddot{\theta} = -mgl\sin{\theta} + u + \tau_d,
\]

where \( m \) is the mass of at the end of the pendulum, \( \theta \) is the angle of the pendulum with respect to vertical, \( l \) is the length of the (massless) rod that connects the mass to the pivot at the top, and \( u \) is an input torque. \( \tau_d \) is an unknown disturbance torque acting on the system. A sensor measures \( \theta \) according to a measurement \( \theta_m = \theta + n_\theta \), where \( n_\theta \) is a stationary, zero-mean, Gaussian-distributed variable with standard deviation \( \sigma_\theta \).

(a) Write the dynamics as a state-space nonlinear function, and provide the \( A, B, C, \) and \( D \) matrices of the system linearized at \( \theta = 0 \). Show that the system is observable.
(b) To formulate a Kalman Filter, the system must have imperfect (noisy) sensors and may optionally be excited by a non-zero disturbance. Provide the $G$ matrix corresponding to excitation by the disturbance torque $\tau_d$ given in the equation above.

(c) Write a simulation of this system’s nonlinear dynamics, and implement a Kalman Filter to estimate its state from measurements $\theta_m$ (note: this problem entails estimation, but not control). If you are stuck, it may be helpful to consult the file `me586_example_kalman_estimator.ipynb` on the software_examples section of the course web page for an example implementation of a Kalman Filter on a different system. Please use the following constants:

<table>
<thead>
<tr>
<th>Variable</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>$m$</td>
<td>0.1 kg</td>
</tr>
<tr>
<td>$l$</td>
<td>1 m</td>
</tr>
<tr>
<td>$\sigma_\theta$</td>
<td>0.1 rad</td>
</tr>
</tbody>
</table>

**Note:** estimating the standard deviation $\sigma_d$ of the disturbance noise $\tau_d$ is difficult in practice, so in this problem you will instead use it as a tuning knob to achieve desired performance.

(d) For an initial angle of $\theta = 1$ rad, your Kalman filter should follow the true state of the pendulum relatively well. Provide a plot in your Jupyter notebook. Then, in a subsequent cell, re-simulate the system with an initial condition of $\theta = 2$ rad.

(e) Why does a larger excursion result in larger error in your Kalman Filter estimate?

![Figure 1: Sensors of the quad-rotor Crazyflie with the “Flowdeck” sensor.](image)

2. **State estimation and LQG control of a 2D simulated quadrotor**

A complete Linear Quadratic Gaussian ("LQG") control system consists of an LQR controller and a “Kalman Filter.” You will implement an LQG controller for 2D quadrotor dynamics for a Crazyflie equipped with a “flowdeck” sensor board.

To implement a Kalman Filter, we must first ascertain whether our system is observable at equilibrium. To do that we must linearize the observation model. The onboard gyroscope measures angular velocity, providing a measurement $\omega_m$, the time-of-flight sensor provides a measurement the distance to the surface below the helicopter $r_m$, and the optic flow sensor provides an optic flow measurement $\Omega_m$, according to the following models

\[
\begin{align*}
\omega_m &= \omega + n_g \\
r_m &= r + n_t \\
\Omega_m &= \Omega + n_o = \omega - \frac{\dot{x}'}{r} + n_o,
\end{align*}
\]
where each \( n \) corresponds to noise added to the sensor reading, which we assume is zero-mean Gaussian white noise. The quantities \( \dot{x}' \) and \( \dot{y}' \) are velocities given in body-attached coordinates, and are the components of the velocity vector \( \mathbf{v}' = R^T \mathbf{v} \). These quantities are depicted in Figure 1.

(a) For the downward-oriented optic flow sensor, find the optic flow as a function of your state \( \Omega = \Omega(\theta_y, \omega_y, x, \dot{x}, z, \dot{z}) \). To do this you will need to find the relation for the distance \( r \) to the ground (as a function of \( \theta_y \) and \( z \)) as shown in Figure 1.

(b) Now suppose the robot is hovering near equilibrium near the desired height \( z_d \), that is, \( \mathbf{q} = [\theta_y, \omega_y, x, \dot{x}, z, \dot{z}]^T = [0, 0, 0, 0, z_d, 0]^T \). Show that the linearization of the nonlinear observation model \( y(q) = [\omega, r, \Omega]^T \) at equilibrium is given by the observation matrix

\[
C = \begin{bmatrix}
0 & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & 0 \\
0 & 1 & 0 & -\frac{1}{z_d} & 0 & 0
\end{bmatrix}
\]

(c) Show in your notebook that with the \( A \) matrix derived in the previous problem set, that such a system is not observable by computing the observability matrix and its rank.

The reason for this is that the optic flow sensor does not measure position, only velocity, meaning that the state \( x \) is not observable in the strict sense. The math that calculates the gains \( L \) of a Kalman filter, however, requires that the system be observable. So we will instead create a "reduced" linearized model of our system that does not include its non-observable \( x \)-position. The pair \( (A_r, C_r) \) of these reduced matrices are observable, and are given by

\[
A_r = \begin{bmatrix}
0 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 \\
g & 0 & -\frac{b}{m} & 0 & 0 \\
0 & 0 & 0 & 0 & 1 \\
0 & 0 & 0 & 0 & -\frac{b}{m}
\end{bmatrix}, \quad C_r = \begin{bmatrix}
0 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 \\
0 & 1 & -\frac{1}{z_d} & 0 & 0
\end{bmatrix}
\]

(d) The matrix \( G \) specifies how disturbance noise \( d \) enters the system. This can be set to the identity matrix, but it typically is set to represent a realistic model for what noise might enter the system. Here, we will assume that there are three sources of disturbance arising from wind currents: a) force in the \( x \)-direction, b) force in the \( z \)-direction, and c) rotational torque around the \( y \)-axis. Show that if the disturbance is specified in units of [Nm] for torque and [N] for force, then \( G_r \) is given by

\[
G_r = \begin{bmatrix}
0 & 0 & 0 \\
0 & 0 & \frac{1}{J_{yy}} \\
\frac{1}{m} & 0 & 0 \\
0 & 0 & 0 \\
0 & 0 & 0
\end{bmatrix}
\]

(e) In the Jupyter notebook `me586_2d_crazyflie_simulator_LQG.ipynb` on the software examples section of the course webpage, we will use an estimator that is augmented by adding a row of zeros to the \( L \) matrix on the row corresponding to the \( x \) position state in the full system. Having a zero row in \( L \) like this means that the estimator applies corrections to all of the observable states, while not applying any corrections to \( \dot{x} \), which is not observable. But we will use our dynamics model to still provide a prediction of \( \dot{x} \) that comes from numerically integrating the velocity. This estimate will slowly drift from its true value due to sensor noise, but represents our “best guess” of position that we will use for feedback control.

Finish implementation of the Kalman Filter (LQE estimator) by filling in missing elements (between comments with three `###`‘s.) You will need to add an extra row (in the right location) to your \( G_r \) matrix as well. A suggested LQR controller is also implemented that does not need to be changed. As in the previous problem, the size of the sensor noise is known but the disturbance noise size is much harder to measure and therefore becomes your “tuning knob.” Explore how
changing weights affects the behavior of the system, increasing or decreasing the weights in the process noise matrix $Q_N$ until you get reasonable estimator performance. Provide a plot in your notebook that shows the system estimating the state of the system under control of an LQR controller that is operating using feedback from the true state rather than the estimated state (this is usually easier to get to work correctly).

(f) Next, close the loop, giving your LQR controller the Kalman Estimate, and provide a plot showing your results.

**Tip:** The Kalman filter has a lot of moving parts and can show erratic behavior if gains are too high. One thing you can do to help isolate such problems is to reduce the time increment $dt$ of your simulation to get a more precise dynamics simulation.

(g) Lastly, provide plots that show your system subject to the following effects and briefly (in a sentence or two) explain:

i. What happens when the disturbance noise in the $x$-direction is much higher than the disturbance noise in the $z$-direction?

ii. Why does the position estimate have an error if the altitude is not exactly equal to $z_d$? (such as if you start above or below $z_d$) Can you suggest an approach you could use to fix it?
